LECTURES
ON
DISEASES OF THE CHEST,

In the course of which the Application of
PERCUSSION AND AUSCULTATION
ARE FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE I.

THE course of lectures, gentlemen, which I am about to deliver to you, naturally divides itself into two parts—first, diseases of the chest; and, secondly, diseases of the abdomen. I shall commence with the

DISEASES OF THE CHEST.

There are few subjects, connected with the study of medicine, of greater importance than the diseases of the chest; and they derive that importance from a variety of circumstances; some of which I shall detail.

In the first place, there are certainly no diseases of such frequency; for I may truly say that there scarcely exists the individual in this climate who has not, at one period or other of his life, been subject to some form of pulmonary disorder—nay, I may even say still more, there perhaps scarcely exists the individual in these latitudes who is not even *annually*, more or less, affected in this way.

Neither is there any class of affections which produces so great a positive mortality. I say *positive*, not *comparative*; because the diseases of the organs contained in the chest are not more fatal than those of the brain, or the abdominal viscera, but it results from their extreme frequency. It is true that the data which we possess, by which we judge of this, are insufficient, as medical statistics have been, unfortunately, too little cultivated in this coun-

try; but those which we do possess, err, I am quite satisfied, on the side of omission, rather than of exaggeration. From the London bills of mortality, we see that more than one-third of the annual mortality of this metropolis depends upon pulmonary disorder; and if we take into consideration the number of cases of dropsy, and the many cases of apoplexy, depending upon diseases of the heart, I am quite sure we should come nearer to the mark were we to say that one-half of the mortality depends upon affections of the pulmonary or cardiac systems.

In the next place, their complication with other diseases is a subject of great importance; for you scarcely find any general disease, especially of a febrile kind, in which the lungs and heart do not more or less participate. So sure as the skin becomes hot or cold, the mucous surfaces of the trachea and bronchi will sympathize with it. You will find no case of fever in which there are not some signs of pulmonary lesion. Chronic diseases occasioning great debility, often predispose to phthisis; and I need not say how the motions of the heart are accelerated in fevers, or are influenced by many other affections.

But to us, as medical men, there is another important reason why we should study these diseases. The signs by which we have hitherto judged of them, have been, as I shall shew you, extremely equivocal. I say *equivocal*, because one sign may be common to various conditions of the lungs and heart. In the middle of the last century a discovery was made, by Avenbrugger, by which these diseases could be more specially determined; and the means of doing so were enlarged by the still more brilliant discoveries of Laennec. He, or rather I may say they, have thus rendered the diagnosis of the diseases of the heart and lungs almost as clear, almost as distinct, as the external or surgical diseases of the body.

When you reflect, therefore, upon the

extreme frequency of pulmonary disorders,—of the mortality they occasion—of their complication with other diseases—and, finally, of the extreme importance of the new mode of investigating them—I need say no more to stimulate you to the highest exertion in prosecuting the study of this subject.

It might not be, perhaps, uninteresting at this moment, to cast a general view over the causes of this extreme frequency of thoracic disease. I do not mean to enter here into a minute detail, because I must do that when I arrive at each particular subject. In the first place, in the lungs you have a most delicate organization, consisting of an immense number of cells, extremely thin, so that from their mere texture it is not a matter of surprise that these organs should become frequently affected. But when you superadd that that texture is in constant movement—a movement which commences at the moment of birth, and only terminates in an existence of longer or shorter duration—a movement proceeding at the average rate of seventeen or eighteen respirations in a minute, and each of which, you will recollect, is not a single, but a double action, the one of inspiration, the other of expiration—so that you have no less than thirty-four or thirty-six movements going on in that time—I say, therefore, that the frequency of these motions in so delicate a texture, must strongly predispose these organs to disease. Consider, also, the nature of the functions which the lung has to perform; on the one hand, receiving blood, varying frequently in quantity—varying in the force with which it is received from the heart, and varying also, doubtless, in its quality; and on the other hand, receiving atmospheric air, varying also in quantity, quality, and, above all, in temperature;—taking all these circumstances together, you see the numerous causes there are to account for the frequency of diseases of the lungs.

The heart, again, is an organ delicate in its texture, considering the function it has to perform. It has constantly to overcome a resistance, because its office is to propel forward a fluid; this office commencing at the earliest period of embryotic existence, and terminating only in a life of varied duration. Too slow or too frequent a pulsation, may equally be a cause of derangement.

We see that the average rapidity of the heart's contractions is seventy or eighty in a minute, and that each ventricular beat is followed by a ventricular dilatation, which I think I can prove hereafter to be effected by an active expansion; so that the movements are in reality double the number of the arterial

pulsations, or 140 or 160 in that time. We see also that these motions are influenced by a variety of circumstances, as general disease, labour, exercise, emotions of the mind, &c.: some of the passions accelerating the heart's actions to an extraordinary rapidity; others, as profound grief, depressing them almost to cessation. Considering all these circumstances, it is a matter of surprise that this organ is not more frequently affected.

It might be expected, perhaps, that I should enter here into an historical account of the rise and progress of our knowledge in pulmonary and cardiac diseases, or that I should give what is called an *historical lecture*. Were I to do so, I must suppose that all the gentlemen whom I have the honour to address are acquainted with the subject; I know that many of you are, but it is my business to suppose that I am addressing those who are perfectly ignorant of it; and were I to give a history, I must enter into details, and employ technical expressions, which I must assume you do not understand, and therefore I shall give as much of the literature as will be necessary to elucidate the subject, when I come to each particular part.

I shall now proceed to lay down the plan which I intend to follow in the course. I propose to treat of diseases of the lungs and diseases of the heart: the course, then, divides itself into two sections—first, diseases of the lungs, which will comprise about twenty lectures; and, secondly, diseases of the heart, which will occupy about six or seven.

We commence with

DISEASES OF THE LUNGS.

This portion of the course may be divided into two parts—first, the *Theory of the Signs* of pulmonary affections; secondly, the *Diseases* themselves—the latter section admitting the anatomical arrangement of diseases of the air passages, diseases of the parenchymatous substance, and diseases of the pleura.

THEORY OF THE SIGNS OF DISEASE OF THE LUNGS.

I shall now proceed to the consideration of the theory of the signs of the diseases of the lungs; and it may be asked, and very naturally, why I prefer commencing with this subject rather than with the diseases themselves. It is because there are many generalities which can be made in relation to these signs, particularly on the subjects of dyspnoea, percussion, and auscultation, easy to be understood at once, but which involve many principles and technical expressions

which would constantly embarrass us were we to defer their explanation until we arrived at their application to each particular disease. Experience has shewn this to me as the best plan, and I think you will soon discover this as we proceed.

Let us now endeavour to arrange the signs: I think the following order the best, as the lines of demarcation are tolerably distinct; and it applies as well to the rest of the diseases of the body as to those of the lungs.

First, *functional signs*. By a functional sign I mean a sign which arises from a disordered condition of the function of the organ.—Secondly, *local signs*. A local sign is that which is detected by a local examination of the organ.—Thirdly, *general signs*. By these we mean when two or more of the rest of the functions of the body are deranged in consequence of the disturbance of a particular organ. This arrangement, as I have just said, applies to all the diseases of the body; but as examples are infinitely better than mere definitions, I will give you a few to show what is meant.

A functional sign is a sign arising from the lesion of a function. For instance, I will suppose the eye to be inflamed. What is the first thing you observe? Why, that vision is impaired. There is a change here in the function of the organ, and that would be a functional sign. I examine the eye; I see, perhaps, redness of the tunica conjunctiva. This is a local examination of the organ; and the redness of the conjunctiva is a local sign. Suppose, in consequence of this disease, febrile symptoms arise; the pulse becomes excited, beating quickly; the head affected; and the skin heated. Here are several functions of the body disturbed in consequence of the derangement of a particular organ. These are the general signs. I will suppose a case of a common sore throat—cynanche tonsillaris. The first sign is a difficulty of swallowing—the function is disturbed, and that difficulty would be a functional sign. I examine the throat; I see the tonsil swollen and red. This swelling and redness are local signs. General febrile action would be set up under such circumstances, or the rest of the functions of the body would be disturbed in consequence of the lesion of the tonsils; and these constitute the general signs.—To exemplify it by a disease of the chest: suppose a case of peripneumonia, or inflammation of the substance of the lungs. The first thing I observe is a difficulty of breathing, *dyspnœa*; that is a functional sign. By percussion and the stethoscope I examine the chest, and I find certain sounds, and these would be

local signs, and the general febrile action would be the general signs.

I shall not fatigue your attention with more examples, otherwise I might go through the whole of pathology, and give instances throughout of the general application of this simple division.

We will now commence with the theory of the signs of the diseases of the chest, by describing the

THEORY OF DYSPNŒA.

Dyspnœa is the first great functional sign of disease of the chest: to this I must request your especial attention.

By dyspnœa we mean an aberration from the normal condition of respiration, or, to use language less scientific, simply difficulty of breathing; but I would rather extend the term dyspnœa. It is generally used to express mere rapidity of breathing; but I would say that *any* aberration from the usual condition of respiration constituted dyspnœa: if the breathing were too slow, that would be to me dyspnœa, or difficulty of breathing.

Having given you this definition, I shall next attempt to establish a theory by announcing the following proposition, and then I shall endeavour to prove it; which is, that dyspnœa is nothing more or less than an effort of nature to establish an equilibrium between the quantity of the air and the quantity of blood in the lungs.

Before I proceed to establish this proposition, I must, in the first place, recal your attention to some of the leading points connected with the anatomy and physiology of the lungs and heart. The lungs are to be considered as a double organ, one placed upon each side of the chest, connected together by means of a tube called the *trachea*, which splits at its inferior extremity into two branches, denominated *bronchi*, one of which goes to each lung, and each has for its function the carrying of air into that organ. These bronchi ramify, and terminate in capillary extremities in the vessels or air-cells of the lungs. Between the lungs is placed the heart: it is situated in the lower part of the cavity of the chest, and inclining obliquely to the left side. The heart is of a conical form, having its base uppermost, and its apex below. This viscus is divided into two parts, or a right and left side, by a central septum: it is also divided into two parts, according to its transverse diameter, the upper and lower; the upper portion being called the *auricles*, the lower part the *ventricles*; and the terms right and left being applied to these cavities according to their relation to the perpendicular septum.

Now, what is the use of this organ?—The heart may be considered as a vessel divided into four parts or cavities, for the purpose of receiving the blood from all parts of the body, and for propelling that blood onwards. Let us trace the blood in its course.

The arterial blood, of a vermilion red colour, and fitted for the purposes of secretion and nutrition, is carried from the lungs by the four pulmonary veins into the left auricle, and thence into the corresponding ventricle, from which it passes into the aorta, and all its branches to their capillary terminations; and, by the beautiful mechanical arrangement of the mitral and semi-lunar aortic valves, it is prevented from retrograding in its course in the heart. The arterial blood deposits its secretions, and adds nutriment to the living fibre at the extremity of the aortic system of vessels, and is now diminished in quantity in proportion to those deposits, and changed in other qualities; it becomes of a darker red hue, and is called venous; is unfitted for the purposes of secretion (excepting of the bile), and of nutrition, and requires renovation.

This renovation is effected in its transit back again to the heart, by the chyle and lymph being poured into the venous system, and by the blood being carried afterwards into the lungs, to be there exposed to the oxygen of the atmospheric air: by the united influence of these causes it is restored to its arterial qualities, and is again fitted for its important functions. But how is it carried to the lungs?

From the arterial capillaries arises another system of vessels equally minute, which unite in larger and larger tubes as they approach the heart, until they finally terminate in the right auricle by two large vessels, which are denominated *vena cavae*. These vessels are called veins; the blood within them flows more tardily than in the arteries; and as if the force which moved the venous blood were insufficient to carry it to the lungs and round the pulmonary circulation, the right side of the heart seems placed intermediately to receive it, and to give it sufficient impetus to be transmitted to its ultimate destination.

The blood, then, of the *cavae* is carried into the right auricle, ventricle, and pulmonary artery, to the minutest ramification of the latter vessel, and from thence to the system of pulmonary veins. A similar arrangement of valves exists in the right side as well as the left, under the names of tricuspid and pulmonary semi-lunar valves, and for a precisely similar purpose, to prevent the retrogression of the blood.

You thus see here one pulmonary artery

to carry the blood into the lungs, and one tube or trachea to carry air; but the venous blood, when changed, passes by a different set of vessels, the pulmonary veins, while the air returns by the same vessel, necessitating a double act in the latter,—the one of inspiration, the other of expiration.

Now, to examine the subject still farther, we must inquire, What are the elements essentially necessary to the healthy condition of the circulation and respiration? There are two; there is the blood on the one hand, and the air on the other; there is blood to be changed, and there is air to be carried down to change it.

With regard to the blood, every time that the right ventricle propels it into the lung it must be effected in due *quantity*. I cannot state the quantity, for it must be various in different individuals, and at different ages; but there must be a due quantity in relation to the quantity of air; and therefore we will note down as our first element, *quantity*. In the next place, the blood must certainly be conveyed with due *force*. If the force be too feeble, it is very evident that it will not propel the blood sufficiently onwards; if it be too strong, the contrary will be the effect, and therefore *force* must essentially be an element here. In the third place, there must certainly be a given *time* for each pulsation. The heart may beat thirty or forty times in a minute,—that is too slow; or it may beat 150 times in a minute,—that is too quick; and therefore *frequency of pulsation* must be considered as an element. In the next place,—although this is a subject which we do not yet well understand,—there can be no doubt the blood should be of a certain *quality*. And, finally, there must be a *vessel of due calibre* to convey the blood. *Capacity of vessel* may therefore be considered a necessary element.

These, then, are the necessary elements of the healthy circulation of the blood,—due quantity, a given force, a due relation of time, a given quality, and a proper capacity of the vessels.

Then, with regard to the air, you will find the elements here exactly the same as in the case of the blood. There must be a due *quantity* of air to decarbonize a due quantity of blood. *Quantity*, then, will be an element.

We may give an instance of this. In breathing upon a plain, we will say at the level of the sea, where the atmosphere is of the greatest density, from receiving the greatest possible pressure, we will suppose that a cubic inch of air contains a given quantity of oxygen: but ascend a mountain, the pressure of the atmosphere be-

comes less, and consequently there is less oxygen in the same space; the breathing then becomes quick; and therefore it is evident that quantity forms an element. Then the respiratory acts must be effected with a certain *force*, otherwise the lung would receive too great or too small a quantity of air. There must also be a given *time*. The ordinary time is about eighteen respirations in a minute; but, suppose there be only one-half that number, the patient will experience great difficulty. Try it yourselves. Reduce the respiration voluntarily to four or five times in a minute, and you will soon feel great distress; from which it is evident that time is an essential element. The *quality* of the air, no doubt, is another element. I am not speaking of poisonous gases, such as sulphuretted hydrogen, but of those which are noxious only from the absence of oxygen, such as carbonic acid and azote. Finally, there must be a due *capacity* of the trachea and the lungs, to admit of sufficient air to oxygenize the quantity of blood sent by the pulmonary artery.

Now let this be understood, and what we are about to say becomes exceedingly easy of comprehension. There must always be a due relation of these elements to each other; for if there be not, you will have dyspnœa as the result. If the quantity of blood in the lungs be increased, there will be an attempt to increase the quantity of air; and that can only be effected by accelerating the respiratory acts; and therefore I repeat, that dyspnœa is an effort of nature to establish an equilibrium between the quantity of air and the quantity of blood. But I will state a number of examples which will incontestibly prove the truth of my proposition. They shall first be in relation to the heart, and next to the lungs.

You know that if a person runs, he soon gets out of breath, or into a state of dyspnœa. What is the cause of this? The venous blood is now precipitated with greater rapidity to the right side of the heart, and from thence to the pulmonary artery and lungs, so that the force and velocity of the circulation is increased; by consequence the quantity of blood in the lungs is also increased in a given time, so that we have here the elements of force, velocity, and consequent quantity, in excess. What results? The respiratory acts become also accelerated; they are effected with greater force and rapidity, and more air is received into the lungs, in a shorter time. Nature here, then, endeavours to create a due relation between the force and velocity of the movements of the two organs, for the purpose of establishing an equilibrium between the quantity of the blood and the quantity of the air.

Let us now suppose a case of diseased heart (referring to a diagram)—that the calibre of the aortic orifice be diminished, either by congenital error of formation, or by diseased valves. The blood arrives in due quantity to the left ventricle, but the aorta, or discharging tube, is of too small a *capacity* to allow it to freely pass; what takes place? The blood must accumulate in a direction posterior to the obstruction, and retrograde to the current of the circulation. Thus, then, the left ventricle and auricle become habitually too full, and finally, as we shall hereafter describe, diseased in their parietes; the pulmonary veins to their capillary extremities become also gorged with blood, thus opposing obstruction to the current flowing in the pulmonary artery and the right side of the heart. The result of all this is, that the blood exists in the lungs always in too great *quantity*,—the original cause being the obstruction from the diminished calibre of the aortic orifice. Observe persons affected in this way; they are in a state of habitual dyspnœa; their respiration is constantly accelerated; they are always endeavouring to increase the quantity of air, to establish a relation with the quantity of the blood. Increase the force and velocity of their circulation, by making them ascend an inclined surface, although but a small additional quantity of blood be sent to their lungs, yet their breathing becomes quickened to a sense of suffocation. They are obliged to stop; nature here makes a great effort to restore the balance.

We will now proceed to the lungs, to exemplify the same principles; and we will suppose that the circulation is perfectly healthy. You know that one of the most formidable diseases we have to treat, though fortunately not a very frequent one, is inflammation of the rima glottidis, or opening of the larynx. The rima glottidis is but a narrow orifice; but the result of inflammation there is to contract it very considerably, and the *capacity* of the air tube is diminished at its very commencement, and consequently the diameter of the column of air inspired; so that the quantity of air is insufficient for the purposes of respiration at the usual rapidity of seventeen or eighteen movements in a minute. Dyspnœa arises; the respirations increase to thirty, forty, or fifty, in the same time. We endeavour here to establish an equilibrium in quantity, by multiplying the inspirations in proportion to the narrowness of the column of air. Is not this, then, an effort of nature to establish an equilibrium between the quantity of air and of blood in the lungs?

Croup is an inflammation of the tracheal mucous membrane, having for its result a

secretion which concretes, and forms an inner mould for the larynx and trachea, or a tube within a tube. The column of air must here be diminished in diameter, and is insufficient for the purposes of respiration. It is renewed then with a doubled or tripled velocity—in other words there is dyspnoea, and for the same reasons I have already mentioned.

I will suppose a case of peripneumonia arrived at the second stage, or hepatization, and that it affects half the lung on one side, the capacity of the whole of the lungs would be diminished one-quarter; or if it affect the whole of the lung on one side, then the diminution of capacity would be one-half. Under such circumstances, the rapidity and force of the respirations would be proportionately increased; so that here the elements rapidity and force are in excess, in consequence of diminished capacity.

Any circumstance preventing the free expansion of the lungs, may be said to act by diminishing their capacity; thus fluid in the cavities of the pleura, or in the pericardium, aneurisms of the thoracic aorta, enlargements of the heart, tumors in the chest, all prevent these organs from expanding, more particularly in the transverse, or antero-posterior directions; whilst abdominal tumors, gestation, dropsies, &c. prevent the free descent of the diaphragm, and consequently the increase of the perpendicular diameter of the thoracic cavity.

I need hardly say, that the *quality* of the air influences the respiration. Confine an animal in a vessel in which the air cannot be renewed; and in proportion to the diminution of the oxygen dyspnoea comes on—that is, it increases the frequency and force of its respirations in proportion to the decrease of that gas.

I might, at the expense of fatiguing your attention, easily increase the number of examples, but I hope these are sufficient to prove the proposition I originally advanced, that dyspnoea is an effort of nature to establish an equilibrium between the quantity of the air and of the blood in the lungs.

Are there any exceptions to this theory? There are apparently two; but I think they are only *apparent*, and not real. In some instances, particularly in low fevers, you will find that the pulse is very rapid, but that it is small, and there will be no dyspnoea. You have two elements here, rapidity and quantity, in fault; but if you have the quantity diminished at each stroke of the heart, as the smallness of the pulse would indicate, the increased rapidity may make up for the difference of the quantity which should be sent into the lungs each time; and therefore there is a compensation, and the real quantity is not

greater than it should be, and consequently there is no necessity for a greater quantity of air than usual, and there is no dyspnoea.

The next objection would be, that in some cases the pulse is full and quick, and yet there is no dyspnoea: you see this particularly in cases of inflammatory fevers; but observe the blood as it flows from a vein; it appears half-arterialized; it is much redder than usual, especially if the febrile action be high. What has occurred in this case? the blood seems to be already, to a certain extent, decarbonized. The quality is changed; it does not require so much oxygenation. I only offer this as an hypothesis; but I believe that in consequence of the high degree of the oxygenation of the venous blood, it requires less decarbonization when it arrives at the lungs, and therefore the respiration is not increased in frequency.

What is the value of the sign of dyspnoea? In one sense it has no value; in another it is of the highest importance. Dyspnoea will never determine what is the nature of the lesion; it will not determine whether the lungs be affected, or the heart, for you see it is common to them both; it is common to every disease of the lungs, and to a certain extent to every disease of the heart; and therefore it is an *equivocal* sign;—nay, it even occurs in diseases that are placed out of the cavity of the chest—in dropsy, and even in pregnancy, and therefore I say it is of no value in determining a specific lesion. But it is of the highest importance in a practical point of view, in determining the degree of the loss of equilibrium, and therefore gives the most valuable indications. Such, then, is the general theory, as I apprehend, of the sign dyspnoea.

CASE OF

ILIAC ANEURISM, AND LIGATURE OF THE AORTA.

By JOHN MURRAY, M.D.

Cape of Good Hope.

[Communicated by Sir JAMES MACGRIGOR, Bart.]

On the 22d January last, Joseph Banana, æt. 33, a Portuguese of spare habit, naturally of an excellent constitution, and a sailor by profession, was admitted into the Civil Hospital with a very large firm tumor occupying the right iliac, hypogastric, and inguinal regions. He stated that he thought it must have commenced about eight

months previously, when, after much hard labour and constant exposure to cold and wet in seal and whale fishing, he was attacked with violent pains in the right thigh and leg, which he considered to be rheumatic. These, however, did not prevent him from continuing at work; and he was not aware of the existence of any tumor till some months afterwards, that (in the beginning of October last) he was obliged to walk twenty-two miles, and imprudently bathed himself in a river while in a state of profuse perspiration, after which his right thigh and leg became very stiff and painful, and he discovered a small tumor in his groin, about the size of a walnut. Still, however, he was able to go about and to work, although with pain and difficulty, till about a fortnight before entering the hospital, when the tumor began to enlarge suddenly and rapidly, with a strong pulsation, which was perceptible outside his clothes, and accompanied with such acute pain in the limb, groin, and loins, that he was no longer able to walk; at the same time his bowels became obstinately costive, and he had a constant desire to micturate.

The tumor now presents the greatest size and prominence immediately above Poupart's ligament, in the site of the external iliac artery. The most prominent part is tense, shining, and circumscribed; about the size of an orange, and its hard irregular base extends upwards to an imaginary line drawn from the umbilicus to the lower ribs, and downwards to a couple of inches below Poupart's ligament; its lateral boundaries being formed by the ilium and linea alba. Pulsation is felt in the prominent part of the tumor, and a sort of whizzing sound is indistinctly discovered in it on the application of the ear or stethoscope; but there appears to be no circulation in the femoral artery. He does not complain of much pain in the tumor at present, but says it is often exercisingly severe along the thigh bone, and in the knee. The limb is much swollen, and he keeps it constantly in the bent position, and cannot bear to have it extended. The skin is nearly insensible to the touch, and even to pinching, particularly on the inner part of the thigh; yet he describes having a feeling as if worms and flies were creeping over it. Temperature of the diseased limb 92

degrees, and of the sound one 97. Pulse 96, and intermittent; and the action of the heart has a corresponding irregularity. Two or three days ago he had an attack of epistaxis. Tongue covered; respiration natural; intellect clear. Has had scarcely any sleep for many nights, and no motion in his bowels for eleven days.

Ordered two Compound Colocynth Pills; with a spirituous lotion to the tumor.

January 24th.—His bowels have acted from the pills, and he had some refreshing sleep in the night. The leg has become more cedematous, and the veins are greatly congested, from the tumor impeding the return of whatever blood goes to the limb. There is now no pulsation in the tumor visible to the eye; but on applying the ear closely, a deep throbbing is perceptible in it, accompanied with a sound as of a fluid gushing past an obstacle. At a consultation called by Mr. Bailey, the surgeon of the hospital (present, Surgeons Bailey and Abercrombie, Dr. Stewart, and myself), the disease was pronounced to be aneurism of the external iliac artery; and it was the opinion that the case was a very desperate one. The tumor evidently extends too high up the abdomen to admit of the common iliac being tied from the right side. An operation on the distal side of the aneurism holds out no prospect of benefit, as the circulation in the crural artery seems to have already ceased; and ligature of the aorta is suggested as affording the only gleam of hope for the patient.

Ordered to be bled to $\text{ʒ} \text{ xij}$; a bandage wetted with spirituous lotion to be applied round the limb, from the toes upwards; and an enema to be administered in the evening.

25th, 8 A.M.—(Another consultation.) He passed a tolerably quiet night, and had some sleep; and he is considered a little better this morning. The swelling of the limb has diminished since the bandage was applied, and the tumor appears flatter. Pulse 94, and more regular; and the action of the heart has also become regular. Countenance more cheerful; the bowels were opened by the enema; his appetite has improved, but he has much thirst. I thought I could distinguish a slight pulsatory thrill in the femoral artery.

He was ordered the following draught every fourth hour :—

R. Liq. Ammon. Acet. ʒvj.; Spt. Æther. Nit., Tinct. Digitalis aa. guttæ x.; Syrup, ʒj.; Aqua, ʒj. M.

26th, 8 A.M.—(Consultation.) At ten o'clock last night he was seized with such agonizing pain in the back and loins, that, although a man naturally possessed of great fortitude, he groaned and roared incessantly for two or three hours, calling out for something to afford him relief. Forty drops of laudanum were administered, and the pain abated at 3 A.M., after which he slept a little at intervals; but he is greatly changed for the worse since yesterday. His features are much more shrunk and exsanguine; the limb has become quite cold and insensible; and the tumor is again enlarging, and assuming a dark bluish appearance at its prominent part. Pulse 128, and small.

The opinion is, that if an operation for tying the aorta is to be performed, there is little or no time for longer delay; it is considered necessary, however, that some natural warmth (as indicating the existence of some circulation) should be restored to the limb before the operation ought to be attempted.

The wet bandage was removed; stimulating liniments, with friction by warm flannels, were ordered for the limb; and sp. ammon. comp. in small doses, with mist. camph. internally.—The draught prescribed yesterday to be omitted.

At noon the consultation met again, when it was found that by perseverance in the application of friction and warmth to the limb, it had regained a natural degree of temperature; but this was attended with such great pain to the patient that he expressed himself annoyed at the continuance of the exertions “to keep him in pain;” still, however, his greatest agony was in the thigh bone and knee. There is no pulsation to be felt in the femoral artery, and the integuments of the foot have a bluish colour.

The expediency of tying the aorta was now most seriously discussed. The death of the patient was evidently fast approaching if that operation should not be performed, and yet it was considered a fearful alternative for him.

Mr. Bailey thought it an operation that no surgeon was warranted in performing, as the only two instances of it recorded had proved unsuccessful; and he believed the chances in favour of its ever succeeding to be so slight, that even should the majority of those present decide upon recommending it, he would operate against his own judgment, and with a feeling that he was not sufficiently authorized to do it.

Mr. Abercrombie likewise thought the operation held out scarcely any prospect of saving the patient's life, and that it would prove unavailing.

Dr. Stewart expressed his opinion, that as the man, in all probability, would die in less than twenty-four hours if his aorta was not tied, he thought the operation justifiable, as it certainly held out some ray of hope to the man, and the only one of prolonging his life.

I agreed with the Doctor, and advised the operation, on the following considerations:—

That from our present knowledge it could not be deemed altogether beyond the resources of the human frame to re-establish circulation in the lower extremities after tying the aorta. That the only two cases of it recorded, viz. by Sir A. Cooper and Mr. James, did not decide positively that the operation was altogether hopeless, and that it could be performed differently, and in a manner more likely to succeed, by not cutting into the cavity of the abdomen. That this was a fair case for putting its chance of succeeding to trial, and might go far to decide the point. That it could scarcely ever be deemed necessary under circumstances more favourable than in the present case, as the patient seemed sufficiently strong to bear it, his constitution being naturally a good one, and not having suffered very seriously from the local disease until within the last few days. He had not been exhausted by hæmorrhage; he had a resolute and cheerful mind, and he was not unwilling to submit to any operation that was likely to afford him relief from agony, and, at the same time, that held out any prospect of saving his life, which he was now quite aware to be in imminent danger. I said, however, that I could not think of urging my advice, as Mr. Bailey did not feel in his conscience that he was warranted to per-

EXPLANATION OF THE ENGRAVING.

- a*—Aorta.
b—Inferior mesenteric artery.
c—Ligature on the aorta.
d—Right internal iliac.
e—Probe introduced into the upper end of the external iliac.
f—Femoral artery.
g—Crural nerve.
h, h—Imaginary line in the direction of Poupart's ligament.
i—Probe introduced into the lower end of the external iliac.
k—Layers of the sac held open by quills.
l—Between these lines gangrene had commenced.

form the operation. Mr. Bailey replied, that for the reasons he had before stated, he confessed he would rather not perform the operation, as he could not reconcile his conscience to it; but said, that if I chose to undertake it, he was willing to assist me. I begged for a short time to consider, when, having made up my mind, I agreed to perform it in the afternoon; but the absence of Mr. Bailey, who had been called away, and detained in attendance with a serious case, occasioned its being delayed till eleven o'clock at night.

The patient, in the interim, continued in much distress, and was gradually getting worse; the limb was cold, although warm applications were continued to it, and the integuments of the instep and back part of the leg were getting discoloured; the pains in the loins, thigh bone, and knee, were undiminished; his countenance was becoming more anxious, his pulse more feeble and frequent (120), and he was very restless. An enema was administered, which brought away a scybalous motion; he drank a cupful of coffee with relish; his bladder was emptied by a catheter, and he had fifty drops of laudanum given him before the

Operation—which was performed by candlelight, and as he lay in bed, that he might not be put to the pain of being moved before and after it.

The size and position of the tumor precluding the possibility of reaching the aorta by cutting from the right side of the abdomen, rendered this necessary to be done from the left, which fortunately, at the same time, had the advantage of affording the readiest and easiest access to the vessel, on account of its anatomical situation, but greatly increased the difficulty of reaching the right common iliac, to tie it, which it was hoped might be found possible.

The patient lying inclined to the right side, the first incision was commenced a little in front of the projecting end of the tenth rib, and carried for more than six inches downwards, in a curvilinear direction, to a point an inch in front of the superior, anterior, spinous process of the ilium, its convexity being towards the spine. The skin, the subcutaneous cellular tissue, and the aponeurosis of the external oblique muscle, were first incised; next the fibres of this muscle; and successively afterwards the layers of the internal oblique

and transversalis muscles were displayed and divided; which was found rather a delicate part of the operation, as their fibres contracted spasmodically when touched by the scalpel. The fascia transversalis was now brought beautifully into view, and cautiously divided by a pair of scissors upon a director, to avoid wounding the peritoneum. This membrane being now completely laid bare to nearly the whole extent of the external wounds, was next detached from the fascia covering the iliacus, internus, and psœ muscles, chiefly by the hand, introduced flat between these parts, to separate the loose cellular substance connecting them, which was easily effected.

Whilst detaching the peritoneum in the fossa of the psœ, I found my fingers get into a soft pulpy mass, and a good deal of dark bloody fluid began to ooze out by the side of my hand, which made me withdraw it and examine the parts, by throwing a ray of candlelight into the bottom of the wound, when, from the dark appearance of the parts, my first impression was that they were in a gangrenous state; but I soon discovered that it was caused by ecchymosis, or effusion of bloody serum into the loose cellular texture. I then re-introduced my hand, and gradually prosecuted the detaching of the peritoneum in the direction of the spine, till I came to a large pulsating vessel, which I found to be the upper part of the left common iliac, and in another minute the aorta itself was under my finger; to satisfy myself of which, I requested one of the gentlemen assisting me to place his ear on the tumor, and his hand on the left femoral artery, when he heard and felt the pulsation to stop, and recommence in each, as I compressed the vessel, or the contrary. I now endeavoured to reach the right common iliac, but found that the walls of the tumor extended nearly close up to the bifurcation of the aorta; and even had this obstacle not existed, I do not think there is scope for the hand to perform the necessary manipulations to place a ligature upon that vessel from the left side, without using a degree of force, and causing a laceration of parts, that would be inconsistent with due professional caution, humanity, and judgment.

A tedious and rather difficult part of the operation succeeded; viz. the mak-

ing a division in the aortic plexus of nerves, and in the membranous sheath covering the aorta, to get betwixt the vessel and the spine, which I effected partly by the steel end of an elevator cranii, but chiefly by my nails, *with my mind at my fingers' ends*; and I was not a little rejoiced when I had got a sufficient separation to be able to insert the point of the aneurismal needle beyond and behind it; after which I was soon able to get it, with the ligature, round the vessel, without including any portion of nerve or other extraneous substance. In this manœuvre it was with difficulty that the longest-handled aneurismal needle could be made to reach the necessary depth. The ends of the ligatures being brought out, the aorta was gently raised upon it, which enabled us, by holding up the peritoneal bag, to see this great vessel pulsating at an awful rate.

The noose of the ligature was then gradually tightened, till all pulsation and circulation was found to have decidedly ceased in the left groin; and we anxiously watched the general effect upon the patient whilst this and the second knot were being tied.

The pulse at the wrist, during the time, underwent no sensible alteration either in strength, fulness, or frequency; nor did the vascular organization of the head seem to be abnormally congested or excited by the sudden check to this great stream of the circulation. The tightening of the knot did not seem to occasion him any great pain, nor to cause any unusual sensation or shock in the vascular, nervous, or respiratory systems. His first complaint was, that his left leg had become as benumbed and useless as his right, and that we had done him bad service in laming his good leg, which he did not expect, and lamented it bitterly; and on feeling the aorta, it was found to be full, and pulsating, with very great strength, above the ligature, but empty and motionless below it. The ends of the ligature were now brought out exteriorly, and the lips of the wound drawn together by three sutures and adhesive straps, over which a compress and bandage were applied.

The operation was more tedious than difficult; and being effected chiefly out of sight by the hand, it had not the terrific appearance which that by the method of cutting into the cavity of the

abdomen must have, and it was accomplished with the loss of less than two ounces of blood. At one time, during its performance, he required to get some brandy and water to support him; but when it was over, he seemed quite as well as before its commencement; and the pulse was 128, steady and regular.

In about a quarter of an hour after the operation he felt faint, and the pulse fluttered for a few seconds; but he speedily recovered after drinking a little wine and water. He was now placed in a comfortable position in bed, by putting a pillow under his hams, and raising his shoulders to relax the abdominal muscles; and in doing this we were much surprised, as well as pleased, to find that he had the power of moving both his lower extremities with considerable force.

Pulse, about an hour after the operation, 116, regular and firm. Twelve *Guttæ Nigræ* were administered to him in $\frac{3}{4}$ ss. of camphor mixture.

From the time that the ligature was tied, besides complaining of deadness of the left thigh and leg, he very soon began to express having a painful sensation of distention of the bladder, which gradually increased. A catheter was introduced, by which an ounce of urine was drawn off, and the bladder quite emptied, but without relieving the sensation. A flexible tube was also put up by the anus, beyond the sigmoid flexure, under the impression that there might be flatus in the intestines, and an enema was administered; but still for more than an hour his incessant cry was, "My bladder will burst: why do you not pump my water off?"

January 27th.—About 2, 30. A.M. he became easier, and called for a cigar, which he smoked for five minutes, and said, "All I now want is a bottle of wine by my bed-side." A little more wine and water was given him, when he was left quiet.

6. 30. A.M.—From 3 o'clock he was tranquil, and slept at intervals, till this time. He now complains of severe pain in the lower extremities, and over the pubic region. His countenance is anxious, but less so than yesterday. Pulse 120, equal and firm. Temperature of the right ham, $89\frac{1}{2}^{\circ}$; left, $88\frac{3}{4}^{\circ}$, (lower than that of the right;) axilla, 98° . Tongue dry, and of a dark-brown colour. The aneurismal tumor is softer and flatter than before the operation.

There is very little swelling or tension of the abdomen. He has taken a cup of tea and toast with relish, and it is thought that there is reason to entertain some degree of hope that the operation may succeed, as he is easier, and certainly appears to be in some respects better, than he was before it.

Ordered Pulv. Scammon. Comp. ℥i.
Haust. Seidlitz.

2, 30, P.M.—Mr. Bailey reports, that he administered an enema at 10 o'clock, as our patient's bowels continued very uneasy, and the purgative had not operated: that about 11 o'clock he began to complain of violent headache, with great beating of the carotid and temporal arteries, at the same time that his pulse was scarcely perceptible at the wrist; that there was then also much jactitation of the arms, and rolling of the head, and that his face became covered with a cold clammy sweat.

Brandy, ammonia, and camphor mixture, were ordered to be given at intervals in small quantities, as symptoms indicated; since which he has rallied, apparently from the effect of the stimuli. The respiration is hurried, but the pulse at the wrist has improved, and the action of the heart is strong. Both his legs are quite numbed and senseless; spasmodic twitchings are observed in the muscular fibres of the left thigh; and the livid discoloration in the integuments of the back part of the right limb has increased. He has just taken some soup.

5 P.M.—He has slept a little, and seems refreshed by it; and has taken some more soup, and a glass of champagne. No natural warmth is returning to the lower limbs; they continue *death-cold*, notwithstanding the most careful and constant application of external heat, &c.

9 P.M.—He is sinking fast. Face hippocratic; radial pulse scarcely perceptible, but the heart's action still strong. The spasmodic twitchings in the muscles of the left thigh continue. Respiration very hurried and anxious. He is now passing an involuntary stool.

At 9, 50 P.M. he died, having survived the operation scarcely twenty-three hours.

Dissection.—The lower part of the body having been previously injected from the thoracic aorta with great care, was examined ten hours after death.

The abdominal cavity being opened, it was found that the peritoneum had not been injured in the operation; and it exhibited no marks of inflammation.

The omentum, stomach, intestines, and mesentery, were minutely injected, and sound in their structure.

The bladder was vesicated on its internal surface, and its coats considerably thickened.

The peritoneum and abdominal muscles, where they covered the tumor, were densely united together by its pressure, and quite thin and shining at its most prominent part.

On making an incision through the peritoneum, in the line of the operation, the left ureter was observed to be dilated to the size of the little-finger, yet it appeared to have been uninjured in the operation, having been raised along with the peritoneum.

The aorta was found tied at three or four lines above its bifurcation, and about an inch below the inferior mesenteric artery, opposite to the intervertebral substance between the fourth and fifth lumbar vertebræ. The aortic plexus of nerves had been accurately divided, and the vessel completely separated from the surrounding parts. The ligature was well placed, and included no extraneous substance, excepting two small bits of detached nervous fibre that had probably been torn from the aortic plexus.

The aorta was distended with the wax injection, to within about one-third of an inch of the ligature; a clot of blood intervened between them; and beyond the ligature neither size nor wax had passed, and no particle of either was discernible in any of the iliac, crural, or femoral arteries, nor in any of their branches.

A few drops of the size injection were found in a small anastomosing vessel discovered passing between the inferior mesenteric artery and left internal iliac: it arose about $2\frac{1}{2}$ inches below the origin of the mesenteric artery (from the hæmorrhoidal branch of it, which seemed larger than usual), and joined one of the upper branches of the internal iliac, being in length about two inches, but its calibre was so small, having only admitted two or three drops of the coloured size, that it probably never carried red blood during life. No corresponding vessel was to be found in the right side, nor could any further

anastomoses be discovered between the arteries of the abdominal aorta and those of the pelvis, or lower extremities. To what degree it may have existed between the latter and the arteries of the thoracic aorta, we had not an opportunity of ascertaining, as the body was not prepared for it.

The tumor itself, when exposed to its full extent, was found to reach from an inch and a half below Poupart's ligament to within an inch of the bifurcation of the aorta, overlapping the left common iliac artery, occupying the whole of the iliac fossa of that side, and pressing the kidney nearly double. Being incised, it exposed to our view an immense aneurismal sac, filled with concentric layers of coagulable lymph deposited on its surface, loose coagula of dark blood, and thin brown samies.

From the general condition of the parts connected with the tumor, it appeared as if the disease had been of long standing. The iliacus and psœ muscles were in a state nearly approaching to putridity, and the aneurismal sac itself had been on the point of giving way at two different places—viz. at its upper part (behind the peritoneum) by sloughing, as gangrene had advanced to such a degree that its substance gave way with the slightest touch of the finger; and at its lower and anterior part it was nearly bursting into the cavity of the abdomen, from the extreme distention and attenuation of its parietes, where it was most prominent.

By simple inspection of the inner surface of the aneurismal sac, we could not discover its communication with the artery. A probe was attempted to be introduced into it from the femoral artery, but the crural was found to be so much contracted as not to admit of its passing. By blowing into the femoral, however, with a blow-pipe, an opening was discovered at about half an inch above Poupart's ligament; but as from this upwards there was no continuation of the external iliac, the place of communication with the upper part of the artery was only ascertained by passing the end of the blow-pipe around, and blowing at the same time gently through it, till we found a part from whence the common iliac became inflated, which was more than three inches above the lower opening. In the intervening space between them, no trace of the tube of the external iliac was discernible.

Around the upper aperture several

small spiculae of osseous matter were discovered.

At first it appeared as if nearly the whole of the external iliac was disorganized and involved in the aneurism; but after careful dissection, about two inches of its tube were disentangled from the condensed cellular substance forming the outer layers of the sac, in a sound state; after which, it became confounded with the walls of the aneurism.

The whole of the lower part of this artery, together with the crural, and nearly an inch of the femoral, were in a diseased state, and implicated in the tumor.

The most material parts have been very neatly preserved, by Mr. Bickersteth, the assistant-surgeon of the hospital; and Mr. Bailey has kindly allowed the preparation to be sent to the museum of the army medical department, at Chatham.

I am indebted to Mr. Bickersteth also for the accompanying drawing of the preparation.

REMARKS.—As our knowledge of the human body has advanced, we have been led to place greater confidence in the powers of the animal economy for re-establishing the circulation of the blood by collateral channels, in the event of its natural course becoming obstructed; and surgeons, emboldened by the success which has attended their operations on the different branches of the aorta, and encouraged also by discoveries in morbid anatomy, and by the result of experiments upon inferior animals, have considered that it might not be incompatible with life and recovery to tie this vessel itself.

Thousands of minute vessels carry on a degree of circulation by innumerable anastomoses, independent of the aorta, which are capable of enlarging, to perform the duty of the respective trunks when they become obliterated; and the efforts found to have been made in some instances by nature to accomplish this are truly wonderful. The canal of the aorta has been found obliterated by disease even at its arch, as well as in different other parts of its course, and still sufficient circulation had been carried onwards to the inferior parts of the body, and life preserved. It is true that in such instances nature may have had a long time to prepare the anastomosing vessels for the change, and that the process of collateral circulation was proba-

bly effected in a gradual manner, by a simultaneous and proportionate enlargement of these vessels, or by the formation of new and special ones, as the obstruction in the diseased trunks increased; but this is not the case when we tie an artery for a wound, and it is still rather a desideratum in surgery to ascertain in how short a period of time, and in what exact way, nature prepares these circuitous channels under different circumstances. Much no doubt will depend upon the state of the patient's constitution and period of life, as it is not by the mere impetus of the circulation that the anastomosing vessels become enlarged, or that new channels are formed; but by a process which is as much one of vitality as the growth of the body itself. But I should say that in general collateral circulation is readily established, and in a few hours, after our operation upon very large arteries.

Before Sir Astley Cooper's operation, however, which has been much condemned by some of the profession, I apprehend no one thought that a man could live for any time after the aorta had been tied: it was a bold, but certainly not a rash undertaking, under the circumstances of the case; and it afforded important information; as his patient survived it *forty hours*; and from the heat and sensibility of the sound limb becoming gradually restored, and keeping up to the last, after the operation, there is reason to believe that collateral circulation was re-established in it, although in the diseased limb this process evidently failed, as there was no return of animal heat or sensibility in it, which Sir Astley attributed to the condition of the aneurism preventing the free course of the circulation.

It was with the view of ascertaining exactly what degree of collateral circulation had taken place in my case, that I had the body injected, and from not finding but one solitary minute vessel of communication between the arteries of the abdominal aorta, and those situated below the ligature, as stated in the account of the dissection, my first impression was, that the operation had failed from want of accommodating power or ability in the system to provide against the effects of the sudden obstruction to the main current of the blood; and I was disposed to conclude that the operation never could succeed, even if the patient had no disease be-

sides to contend with; but on a more extended examination and consideration of my case, and all circumstances connected with the subject, I do not feel justified in recording my opinion of it to be so very unfavourable.

As we proceeded in the examination of the body of poor Banana, we had ample reasons for believing that his death was neither occasioned by the injury inflicted upon his general system by the operation, nor by the tying of his aorta, but solely by the effect of his disease; as it appeared that gangrene had commenced in the upper part of the aneurismal sac, and must have existed several days prior to the operation, which accounted for the rapid progress of the constitutional symptoms after his admission into the hospital, and from which it was judged that he would in all probability have died about the time he did, whether the operation had been performed or not.

The operation itself was not attended with any such degree of pain or nervous exhaustion as to stamp it one of unbearable severity, nor was it so speedily followed by mortal symptoms as to induce us to consider it extremely dangerous; for when it was over, our patient was so well that it scarcely left the impression upon our minds of its being one of an extraordinarily formidable nature; and at the distance of ten hours afterwards, we thought him positively better even than he had been for some time before it was performed.

It is not to be overlooked in the three cases now recorded in which the aorta had been tied in the human subject, that the patients were all reduced to such a low state by disease that they were already nearly moribund before the operation was undertaken, and that therefore no parallel can be drawn between them and the cases in which the experiments were made upon healthy dogs, nor between them and the cases discovered in morbid anatomy, where the animal economy most probably had energy as well as time to prepare for the change; nor does it follow that because the operation did not save the lives of either of the three men upon whom it has been performed, that it would fail in a person whose local disease had not made irremediable progress, and whose vital energies were not undermined.

It is more than probable, however, that the operation will never succeed in a case of aneurism, as the patient must

be far advanced in danger before he could with propriety be advised to submit to a remedy attended with such imminent risk; and when the disease has advanced so far, the period at which there might be a chance of recovery from the operation is in all likelihood already passed; but in regard to the question whether under favourable circumstances nature possesses the power of re-establishing circulation in the pelvic extremities after ligature of the aorta, I would say that it cannot reasonably be doubted; and I can fancy cases of wounds and disease where it might be the only means of saving life, and where, if had recourse to in time, I think it might be employed with hope of success. It certainly has not had a fair chance in any of the recorded instances in which it has hitherto been tried, as the patients had not sufficient health and energy of constitution for effecting the vital process of collateral circulation.

Cape of Good Hope,
Feb. 21, 1834.

MEDICAL REFORM.

OUTLINES OF A PLAN FOR THE FUTURE REGULATION OF THE MEDICAL PROFESSION.

To the Editor of the Medical Gazette.

SIR,

IN offering the following proposal to the consideration of the members of the medical profession, I am fully aware of the arduous task which I have undertaken; and I can only plead in excuse for my temerity, that I have spared no pains to obtain the necessary information on the subject, and that I have used my best endeavours to avail myself of the information thus obtained. My object has been threefold: first, to insure to the public a succession of competent medical practitioners; secondly, to promote the respectability and dignity of the medical profession; and lastly, to encroach as little as possible upon the rights and privileges of existing institutions.—I am, sir,

Your obedient servant,

J. BOSTOCK, M.D.

Upper Bedford Place,
Sept. 20, 1834.

1. A Medical Board to be established by act of Parliament; to consist of five members, of which two shall be medical practitioners; two men of science connected with the medical profession, but not necessarily practitioners, or engaged in practice; one a member of the Government. The members to be appointed by the Secretary of State for the Home Department. The whole five to remain in office for three years; then one member to be changed annually, and to be replaced by an individual of the same description; the new member to be appointed by the Secretary for the Home Department. The Board to have a permanent secretary, who is to be of the medical profession. The members to be remunerated fairly, but not extravagantly, for their services; 1*l.* for every attendance, but the annual sum to each individual not to exceed 200*l.* The secretary to have a permanent salary of 200*l.* per annum; a reasonable allowance to be also made for travelling expenses. A regular account of all the proceedings of the Board to be kept, which may at any time be inspected by proper application. An annual account of all expenses to be printed and published, with the names of all the officers, and the sums of money received by each.

2. Medical practitioners to be divided into four classes:—

- i. Doctors of Medicine, who are supposed to be completely educated in all the essential and accessory parts of the science; the curriculum and necessary requisites pointed out below.
- ii. Masters of Surgery, equally well educated, but to pursue a somewhat different curriculum; this pointed out below.
- iii. Licentiates of Medicine and Surgery; these equivalent to what are now styled general practitioners; supposed competent to the treatment of all ordinary cases, but of less complete education than the two first classes; the curriculum and necessary requisites mentioned below.
- iv. Licensed Druggists, to be occupied in compounding and dispensing medicines; the curriculum and necessary requisites mentioned below.

The two latter departments may be united in the same individual, at the

pleasure of the party, provided he goes through the required curricula, and the necessary examinations.

The department of midwifery may be practised by any of the classes, provided they go through the required preparation and examination.

3. All penal statutes respecting medical practitioners to be abolished; the public not to be compelled to employ certain practitioners in preference to others. The duty of the government, and the object of these regulations, is to provide a sufficient number of competent practitioners, and to point them out to the public: if the public prefer irregular or unauthorized practitioners, they must be allowed to do so.

4. *Medical Universities*.—Any establishment possessing the required number of professors or teachers, giving the required number of courses, the courses being of the required length and extent—there being also a certain number of pupils actually paying fees, and the establishment having existed for a certain number of years—is to be recognized as a medical school, or university. The pupils of such universities are capable, according to the regulations hereafter mentioned, of becoming candidates for degrees or diplomas. The medical board are to decide upon the claims of medical establishments to be admitted into the list of recognized schools or universities.

5. Apprenticeships to be discontinued, and pupillage to be substituted in their place—*i. e.* medical practitioners, of all descriptions, may be allowed to take pupils. The arrangements between the practitioners and the pupils to be discretionary, but the board to have the right of deciding, in each case, how far the terms are available to secure the privileges attached to them.

6. The medical curriculum for each of the four classes to be at least five years; of these, for the degree of doctor or master, three at least must be spent at a recognized medical school or university; and for the degree of licentiate, or druggist, one at least; the remainder of the term under pupillage, during two of the five years, in the three first classes, the students must attend regularly the practice of an hospital. The board to decide upon the size and arrangements of the hospital—whether it be available for the purpose intended; such institutions to

be entitled authorized hospitals. A candidate for the degree of doctor of medicine is to attend the following university courses:—Practice of Medicine, Anatomy, Physiology—of each two courses. Practice of Surgery, Chemistry, Materia Medica, Midwifery, Medical Jurisprudence, and Botany—of each one course. The six first of these courses to be of six months' duration; the lectures to be given five days in the week, each lecture an hour in length; the remaining courses to be of three months' duration. Only four courses, except clinical lectures, can be attended in the same year. An individual proposing to practise midwifery, must, in addition to the other requisites, attend two courses of midwifery in an university, and the practice of a hospital of an appropriate description for one year. A candidate for the degree of master of surgery must pursue the same curriculum with the doctor of medicine, except that he must attend two courses of the practice of surgery, while only one of physiology will be required. The licentiate and the druggist will be required to attend at least one course of the practice of medicine, of the practice of surgery, of anatomy, of chemistry, and of materia medica. Certain foreign universities may be admitted for a part of the curriculum; the board to decide what foreign universities shall be available for this purpose. A student who has gone through the preceding curriculum of public and private education, may become a candidate for a degree.

7. A Board of Examiners to be appointed, to consist of five members, two being members of the Medical Board, the other three being elected from among the professors of the Medical Universities. The Universities may have the privilege of sending a member in rotation; but this not to be compulsory.

8. The existing Universities and Colleges, like other learned bodies, may grant honorary degrees, but a degree conferred by the Board of Examiners is alone to be considered as entitling the party to be styled Doctors of Medicine, &c., and to affix the appropriate letters to their name. The existing practitioners to be invited to go through the new forms, but this not to be compulsory. When a candidate has previously received an honorary diploma, the Board are not at liberty to remit any

part of the ordinary examination at their discretion.

9. For a doctor's or for a master's degree, the candidate is to prepare a dissertation on some professional topic. All candidates are to undergo the necessary examinations in such manner, and in such number, as may be hereafter determined by the Medical Board. The examinations are to be conducted in the English language, but the candidates are to be examined as to their knowledge of Latin. The examinations are to be held in London, twice in the year; in the first week in May, and in the first week in September. A candidate to give a month's notice of his intention to be examined. The candidate to pay 10*l.* for a Doctor's or Master's diploma, and 5*l.* for the diploma of a Licentiate or Druggist.

10. The Medical Board shall have the power of visiting or of appointing visitors for the Universities and authorized hospitals; the time of these visits to be discretionary, but in no case less than once per annum in each institution; detailed minutes to be kept of these proceedings.

11. All elections of medical professors in the Universities, or of medical officers in the authorized hospitals, to be confirmed by the Medical Board.

12. Nothing in this act to affect or interfere with the property or rights of the present Universities or Colleges, except so far as concerns their power of granting degrees, and of prohibiting individuals from practising; in order, however, to enjoy the benefits of the act, they must conform to the above regulations.

13. The above system, in all its parts, to remain in force for the space of five years, then to be revised by a parliamentary commission; the same to be repeated every five years.

TREATMENT OF NASAL POLYPI.

To the Editor of the Medical Gazette.

SIR,

Upon looking over my papers the other day, I found a communication from an old friend and brother officer, on the subject of polypus, which is of too much importance to pass unrecorded. The

paper was transmitted to me in 1833, shortly before a serious illness, or the substance of it should not have been so long withheld from the profession. The article itself is probably too extended for the limits of your journal; but I shall condense it in such a manner, I hope, as to satisfy the author, and at the same time put the profession in full possession of his successful method of treating polypus.

Mr. Joseph Dallaway, divisional surgeon of the Coast Blockade, states that in seventeen cases of common nasal polypi, he has succeeded in curing them all without forceps, or any other mode of treatment than a solution of the sulphas zinci in water, in the proportion of from ʒij. to ʒj. of the former, in ʒj. of the latter. This lotion, he states, is to be introduced up the nostril by means of lint, which has been well moistened with it, and the lint spread over the surface of the tumor, as far up as can conveniently be effected, by means of a probe or director. This lint must be kept moistened by dropping in the solution of zinc four or five times in the day, and then by removing it night and morning, to be replaced with a fresh piece of such moistened lint. Mr. Dallaway states that his seventeen cases were all cured of the disease within a fortnight, by this simple remedy. He does not state, however, that any of the cases enumerated were of a malignant nature, but merely the common soft species of polypus, as I understand him.

Mr. Dallaway first adopted this practice in polypus, he says, so far back as 1797; and aptly remarks, that it *may* be equally successful in certain cases of polypus uteri. I must say, that upon the receipt of this paper, I tried the remedy in my own practice at the Westminster General Dispensary, and in three cases of the soft common polypus I succeeded, within ten days, in removing the disease; and I understand from my colleague, Mr. Thomas Chevalier, that he was equally successful with one or two others.

With every apology to my friend Mr. Dallaway, for retaining his valuable communication so long, I am, sir,

Your obedient servant,

A. COPLAND HUTCHISON.

3, Duchess-Street, Portland Place,

GLOSSITIS TREATED BY INCISIONS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following interesting case worthy the attention of the profession, I shall feel obliged by its insertion in your widely-extended journal.—I am, sir,

Your obedient servant,

C. FERNELEY, M.R.C.S.

Denton, Sept. 15, 1834.

William Jenkinson, æt. 38, labourer, complains this day (July 6, 1834) of stiffness of the lower jaw; difficult deglutition, but little pain; the parotid and submaxillary glands somewhat enlarged; the amygdalæ faucium natural; taste depraved; flow of saliva increased; tongue slightly furrowed, and has small aphthæ on its apex; pulse rather frequent; has but slight febrile symptoms; bowels constipated. He attributes his ailments to drinking cold water when hot. He was ordered to take an aperient immediately; the saline mixture, with antimony, at intervals; to wash the mouth with sage-tea and vinegar, and apply warmth to the enlarged glands.

July 7th.—Pain in the head; the difficulty of swallowing and enlargement of the glands much increased, especially on the left side; tongue swollen, and painful to the touch; skin hot and dry; pulse 100, full; bowels opened.

V.S. ad 5xvi. Leeches to be applied to the throat. Calomel and James's powder to be taken every four hours.

I saw the patient again in about six hours; he had great difficulty of breathing; countenance much distressed; tongue exceedingly painful, and enlarged so as to fill the mouth, which could not be quite closed.

The leeches would not bite. I made three deep incisions on the dorsum of the tongue with a scalpel, each incision being more than an inch in length, and from which several ounces of blood escaped.

To continue the medicine and gargle. To apply a linseed poultice to the throat.

There was almost immediate relief;

in a few hours the swelling of the tongue had much subsided, and he now could articulate plainly.

8th.—Much better; swelling nearly gone. The incisions seem only like superficial scarifications. Has passed a good night: has but little pain. Fever much abated.

To continue the remedies.

9th.—Better.

To omit the poultice to the throat.

11th.—No pain; no fever; can swallow solids. Tongue clean; incisions nearly healed; pulse low and feeble.

To take Sulphate of Quinine in Inf. Rosæ Co. three times a day.

13th.—Much better; incisions scarcely perceptible. Has had, yesterday and to-day, a few occasional spasmodic twitchings in the sterno-cleido-mastoid, and in the muscles inserted into the os hyoides, especially in those of the left side.

15th.—The patient has had no return of the spasm, and to-day went to his usual work.

EXUDATION OF SALT FROM THE SKIN.

To the Editor of the Medical Gazette.

SIR,

As saline exudation occurs rarely, I should feel obliged by the insertion, in the Medical Gazette, of a brief notice of a case in which it took place.

I am, sir,

Your obedient servant,

C. J. B. ALDIS, M.A. M.B.

13, Old Burlington-Street,
Sept. 30, 1834.

Henry Fox, æt. 55, was admitted under one of the physicians of St. George's Hospital on November 9th, 1833, complaining that he was attacked, November 3rd, with dyspnoea, having been previously in good health, though occasionally subject to palpitation of the heart. This was followed by swelling of the abdomen and scrotum; much pain in the chest; cough, without expectoration. Can lie low in his bed, but only on the back. Was sixteen years ago attacked in the same manner.

Pulse 88; tongue whitish; bowels regular; urine very scanty, not a pint having been passed for six days.

November 26th.—Is reported to have perspired very profusely last night. A white powder upon both temples.

27th.—The white powder over a more extended surface.

28th.—Deposit of white powder, as yesterday. The white, apparently saline, deposit very abundant on the face, in points and circular spots. I took some of the saline matter to Dr. Prout, who was kind enough to analyze it, and found the great bulk to consist of common salt.

Swediaur has seen an inveterate case (of gout), in which the patient, labouring under a paroxysm of several months' duration, had the entire surface of the body covered every morning with a white powder, as though he had been dusted with flour*. Dr. Mason Good conjectured that it was urate of soda thrown off by the skin.

MEDICAL GAZETTE.

Saturday, Oct. 4, 1834.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL RESPONSIBILITY— AFFAIR OF M. THOURET-NOROY.

Our brethren in France are once more on the *qui vive* regarding their professional privileges. If we knew nothing of the French beyond their ever-zealous endeavours for their rights, political and professional, we might presume that their code of laws, after such perpetual struggles, must be the most perfect in the world; that a freedom, well-regulated and of an exalted kind, must form its very basis; and that the principles of national liberty must be there so well laid down as to bid defiance to misconception. Yet, perhaps, there is no nation in Europe more unhappily cir-

cumstanced in this respect: no people seem in theory to understand liberty better—none in practice to enjoy it less. They appear to labour under certain unfortunate defects of system. In their anxiety to hedge themselves in from the encroachments of arbitrary power, they become entangled in the meshes of their own legislative refinements: they wish to leave nothing to the discretion of judges and juries; and their code, with all its apparent simplicity and comprehensiveness, either falls short in its practical application to many cases that arise, or requires in each instance the support of *arguments* from the dispensers of justice, which, like most other arguments, always provoke discussion, and often most bitter contrariety of opinion.

The particular case which at present engrosses the attention of our French brethren is one that only justifies the actual excitement by the principle which it involves. M. Thouret-Noroy, a practitioner of respectable standing, has been amerced in heavy damages, by the decisions of two successive tribunals, for alleged malpractice. The strict justice of the case, so far as we have been able to gather the details, does not seem to have been very impartially regarded by the legal authorities; the results, at all events, are unfortunate, and fully warrant the sympathy, as well as the active benevolence, displayed by the profession in Paris. The circumstances tend strongly to show the necessity of having the question of the limits of medical responsibility settled. A more anxious feeling, perhaps, never prevailed on any subject among the several orders of French practitioners; the great majority being pervaded with the laudable desire of obtaining protection from the vexatious and often indecent processes at law, to which they are constantly exposed; and, certainly, if they only persevere in the spirit which seems at this moment to animate

* Nov. Nosul. Meth. Syst. i. p. 213.

them, it were unreasonable not to augur a favourable issue to their exertions.

The affair of M. Thourret-Noroy may be briefly related. This gentleman, a highly respectable provincial practitioner, formerly physician-in-chief to the hospital of St. Quentin, had the misfortune, in bleeding a patient, to open the brachial artery. An aneurism was the consequence, which terminated so unfavourably in the hands of another medical man (one of the lowest rank of practitioners—an *officier de santé*), that the patient had to lose his arm by amputation. An action was brought against M. Thourret-Noroy: the patient was a labouring man, to whom the loss of a limb was a heavy infliction; and the local court of Evreux awarded him ample damages. Such is the bare outline of the case, in which the facts alleged are supposed to have been duly proved; but we must give the reader some idea of the sort of evidence by which the charges were substantiated.

One of the first witnesses for the prosecution, a peasant friend of the plaintiff, stated that it was he who recommended Dr. Noroy to be called in; that he was present during the operation of bleeding; that the blood spouted forth vigorously, and *foamed and frothed* in such a manner that *he did not think it was quite right*. Another man deposed that M. Noroy threw the blood out of the window. After this, some dozen or more witnesses, chiefly villagers and labouring people, were admitted to give *their opinions* on the nature of the tumor: some said it was as large as an egg, and inflamed; others that it was yellow, red, brown, or blue; some, again, affirmed that the Doctor dressed the patient's arm with a fluid which burned wood, reduced linen cloth to powder, and destroyed every thing it touched. Then came M. Chouippes, the *officier de santé*, who told how he was consulted in January 1832 (for so long is this case

pending) by the plaintiff, about a tumor which he had at the fold of his arm. It was four inches in circumference, was pulsating, and could be made to disappear almost entirely by strong compression. By these signs he recognized a *circumscribed and consecutive aneurism*, and advised the patient to undergo an operation, which he (M. C.) performed. The operation did not succeed: two ligatures successively came off in consequence of rupture of the arterial coats; hemorrhages ensued, and ultimately gangrene; so that amputation had to be decided on and practised,—always by the said M. Chouippes. On examining the vessel, he found that it had been incised smoothly by some sharp instrument, which could be no other than Dr. Noroy's lancet. In fine, he asserted that it was *impossible* to wound an artery in venesection unless one was very ignorant of anatomy, or very silly; and that *he* had had in his time ten or twelve operations of this kind to perform, which were rendered necessary by awkward phlebotomists.

On the faith of this respectable testimony a summary judgment was given by the tribunal of Evreux, from which we make the following extract:—

“Inasmuch as the articles 1382 and 1383 of the Civil Code provide for those cases in which there have been awkwardness, imprudence, inattention, and negligence of the most simple and common rules; and especially when, in order either to dissemble, or to repair the consequences of these faults, perfidious, dangerous, or inefficacious methods have been adopted, instead of seeking for safer and better advice:

“Since it has been proved by the complainant Guigne, that Dr. Thourret-Noroy, in bleeding him, opened an artery:

“Since the defendant sought to dissemble, or to repair the injury by the use of means utterly unworthy of the simplest practice:

“And whereas amputation had to be performed on the patient, as the immediate and necessary consequence of

these circumstances, taken singly or in combination :

"The Court condemns M. Thouret-Noroy to pay to the plaintiff, within eight days, the sum of 600 francs, and further to allow to the said plaintiff, from the date of bringing the present action, a life annuity of 150 francs, payable half-yearly."

Such was the harsh, ill-founded, and ill-expressed sentence pronounced by the first tribunal before which the cause was heard. M. Thouret-Noroy of course could not acquiesce in it; he appealed to the superior court of Rouen; but after considerable delay, and the accumulation of much expense, the sentence of Evreux was only confirmed by that of Rouen. The consequences have been almost ruinous to the unfortunate Noroy: were it not for the generous assistance of his professional brethren they would have been wholly so. An execution was levied on his house, and he was stripped of all the little property he had gathered during thirty years of professional life.

In this unhappy condition, his last resource has been to visit the capital, and to implore the aid of the metropolitan practitioners to aid him in applying to the court of *cassation*. The physicians of Paris have come forward, and liberal subscriptions have been entered into. At a public meeting, held on the 18th ult. and at which M. Orfila presided, two resolutions were passed, to the following effect:—1. That a letter be written to M. Thouret-Noroy, expressive of the interest which his professional brethren take in the case in which he has been involved; expressing their approval of his conduct throughout, and encouraging him to pursue his purpose of *cassation*. 2. That a subscription be immediately got up, to defray the necessary expenses of this appeal, and to indemnify M. Noroy for the losses he sustained by the judgments of Evreux and Rouen.

Some further particulars relative to

this meeting may not be uninteresting. M. Sandras handed to the president a letter which he proposed to address, in the name of the assembly, to the Procureur du Roi of Evreux, in order to satisfy his mind, and to convince him that the tribunal had condemned a man who had acted strictly within the limits of the law; while it overlooked the conduct of one who had done an illegal act, and who had really infringed the provisions of the code. This latter remark, as it reflected on the conduct of M. Chouippes, and amounted to an absolute denouement of that person, was objected to by M. Double; who thought that the communication with M. Thouret-Noroy might very well be adopted without attacking the *officier de santé*. But the majority of the assembly were for strongly expressing their opinion of Chouippes.

We think ourselves the majority were in the right. We would not, certainly, approve of *denouncing* the *officier de santé*: but, by all accounts, his conduct in the affair was as unhandsome as it was contrary to law. He broke through all the rules of decency as well as duty, in undertaking those serious operations which he practised on the patient—not only without apprising M. Thouret-Noroy, but calling in no assistance. Besides, he not only ran the risk of so hazardous a proceeding, but voluntarily exposed himself to well-merited censure; for even the most eminent surgeons would not attempt to act as he did, without consulting a brother practitioner, or having professional people to act as his assistants.

M. Dubois d'Amiens also addressed the meeting, and observed, that here there were two questions concerned—the one, which was paramount, related to the responsibility of medical men,—a question on which the meeting ought to express itself strongly; the other had simply a personal reference to

M. Thouret-Noroy. As for the latter, it might be considered as already disposed of; but it had now become so much the more essential to insist upon the first, and to shew decidedly that the tribunals were wrong, inasmuch as that of Evreux had, only two months after its judgment on M. Noroy, reversed its previous decision, in a case precisely parallel—in allowing to a Dr. Dumanoir a medical jury, which it had refused to Dr. Noroy; and in acquitting Dumanoir of the charges brought against him, condemning at the same time the plaintiff to the whole costs and expenses.

It was finally proposed that the letter to M. Thouret-Noroy should be discussed and prepared at a subsequent meeting: the names of subscribers were liberally tendered, the first on the list being that of Baron Dubois, for 500 francs: after which the assembly adjourned.

Having thus given a brief sketch of the "*affaire Noroy*," we would add a very few remarks ere we conclude. Our French brethren, it appears to us, are in this, as in most other affairs of a like nature, very sanguine and perhaps not very sober. Their ardour is not well advised. The privilege of irresponsibility, for which they so zealously contend, is surely not a little unreasonable. *Irresponsibility*, as an attribute of any member of society, is inconsistent and absurd; and if those who are ambitious to possess it, admit (as they must) that they understand the term as of course involving certain limitations, and do not take it in its strict and absolute sense, they ought at least to define those limitations, and inform us exactly what it is they mean.

We recollect that, some months ago, when the *projet* for a re-organization of the faculty was discussed in the Academy of Medicine, a clause was agreed on, almost unanimously, "That medical men should not be responsible for errors committed *without any bad in-*

tention, in the conscientious discharge of their duties." But this did not go far enough for one or two zealous partizans of the irresponsibility principle; they moved as an amendment, though it was not carried, on the ground that it was superfluous, "That *in no case* should medical men be amenable to legal tribunals!" M. Adelon, on the occasion to which we allude, made some pertinent observations. "He would move," he said, "the suppression of the article proposed, because he thought that, in adopting it, society would be left unprotected and exposed to the dangers arising from the negligence and imprudence of medical practitioners. Medical men have been responsible from time immemorial, and yet science has suffered no check; on the contrary, it has made vast strides. Nor is it so very often that the courts of justice are troubled with cases of mal-practice; patients but rarely avail themselves of the privilege they possess, of suing their medical attendants for damages. Latterly, indeed," he added, "there have been some cases of the kind; but it must be confessed that, in the greater number of instances, the defendants have been really to blame."

We quote the words of M. Adelon, as they shew that French practitioners are not exactly agreed on the question of responsibility. We are ourselves far from taking part with either extreme; for though we deny that medical men should be irresponsible, in the sense of our ardent Academicians, and so far seem to side with the Adelon-party, we yet object most decidedly, and as strongly as we may, to making medical men responsible to *such* tribunals as gave judgment in M. Noroy's case. No: we hold that *every* member of society, possessing the faculty of reason, should be answerable for his actions; nor would we have medical men exempt from the general law. But herein

should lie the distinction. Let the medical man for his alleged professional misdeeds (not his *errors*, as the article in the French project would have it) be accountable and responsible;—but to whom? To the only tribunal *competent* to take cognizance of his actions—a jury of his peers. We are aware that even here there would be great difficulties to contend with—the *corpus delicti* being frequently unattainable—the imputed mischief often evanescent—the only witnesses in most cases the parties themselves—to say nothing of the different interpretations capable of being applied to medical transactions, and the unsettled opinions regarding many points of practice, among the members of the faculty. If, however, the French would take a little pains to settle preliminaries of this sort, instead of plunging into eternal discussions on abstract and useless claims, they would save themselves a great deal of trouble, and many a Thouret-Noroy from vexatious and frivolous litigation.

CHOLERA DURING THE LAST THREE YEARS—ITS GRADUAL DECREASE.

It is now two months since we ventured to offer the conjecture, founded on the experience of the last three years, that the malignant cholera had diminished, was diminishing, and would probably be less fatal this season than since its first irruption. The result has fully borne out this anticipation. In 1832, according to the bills of mortality, there were, in July, 1006 fatal cases; in August, 777; in September, 607; giving a total of 2390. In 1833 there were, in July, 181 cases; in August, 853; in September, 199; giving a total of 1233. In 1834 there were, in July, 37 cases; in August, 247; in September, 241; giving a total of 488. And in this last part of the calculation, it is to be observed that the accidental circumstance

of the days of the month falling so as to give five weeks in September, makes the number in this month appear greater than it actually was; so that to allow 307 for August, and 181 for September, would be nearer the truth. The week just terminated gives only 23, whereas in the course of August so many as 103 occurred in one week.

The prospect which the above presents is by no means discouraging, and shews the entire groundlessness of the alarm sounded by one of our contemporaries* some weeks ago; which represented the disease as having broken out in London and other parts of England, with a degree of virulence which exceeded its first onset, in 1832. Nothing can be worse calculated to mitigate the evils of a fatal epidemic than exciting a panic, and we trust that the ridicule which attaches to predictions at once fearful and false, will inspire greater caution in future.

DISEASE CURED BY "COMMAND;"

OR WISE SAWS OF THE MORNING HERALD.

BEFORE we take leave of the subject of cholera, we have a word to say to the *Morning Herald*—a paper, by the way, in which all points connected with medicine are treated in a manner as remarkable for ignorance as illiberality. It is broadly insinuated that the members of our profession have neglected the sick in cholera, from the fear of contagion; than which, an imputation more destitute of truth cannot well be conceived, unless it be the allegation which follows—namely, that "there has been a great supineness apparent upon this important subject." A "great supineness apparent!"—where has the writer lived during the prevalence of the disease?—has he been so much under the influence of terror, that he stirred not from his garret while

the epidemic prevailed? If not, how has he failed to see the members of our profession frequenting, at every hour, the abodes of the poor and destitute, because among them the disease was chiefly to be found; and to whom, regardless of time and toil, they strove to afford relief? Is it *their* fault that the malignity of the malady has hitherto baffled their efforts?—is it to *their* shame that they were suffered to labour unrewarded? or is *theirs* the blame that their efforts have in numerous instances been thwarted, and their motives perverted, by the ignorant conductors of the press?

Again, says the *Herald*, this failure in discovering a remedy for cholera, “confirms an impression which we know is entertained by many persons of the very small advance which medical science has made among us during the last half century.” Is it not astounding that persons so ignorant should be suffered to circulate their pert follies in a paper said to have an extensive sale, and therefore able to employ writers who know at least something of their subject? Medical science made very small advances during the last half century!—Indeed; yet it is within this period that vaccination has been discovered,—that ague has been comparatively banished from England,—that the treatment of fever has been rendered so much more successful than formerly,—that syphilis has ceased to present us with those frightful objects which were wont to shock humanity,—that the great operations on the arteries have been planned and practised,—that the stone has been crushed in the bladder without cutting,—that quinine, and morphia, and iodine, and a host of other powerful agents, have been impressed into our service,—and last, and most especially, that the average mortality has been greatly diminished, and the duration of human life, as shewn by the calcula-

tions of all actuaries, has increased, and is still increasing! But all this avails nothing as long as cholera remains without an antidote; and the *Herald* recommends that “the admitted ignorance of the profession on the subject of this novel desolating scourge should be taken up as a national concern, both in the shape of **COMMAND** and inducement.” Taken up in the shape of *command*!! What can the blockhead mean? Can it be that he thinks there ought to be an act of parliament, or an order in council, ordaining that medical men shall cure all their cholera patients under certain pains and penalties? or is the “command” to be in the shape of exorcism, that the pestilence in question do straightway cease to molest the subjects of these realms, and that its ghost be laid in the Red sea? We have but one suggestion to offer before this be done—let there be a “command” from the proposed quarter that the writer in the *Herald* do quadruple the circle—or discover the philosopher’s stone—or write a sentence of common sense on any subject connected with science—or enact any other impossibility; and when this requisition has been executed, the advice above given may be followed, and a “command” issued to the “Doctors” to cure all cases of cholera.

INTRODUCTORY LECTURES.

PRICE OF PUFFING.

WE regret that we cannot make room for the notices of Introductory Lectures which have been sent us: we advise that they be forwarded to the other journals. We cannot inform our correspondent who makes the inquiry what the expense may be of puffing notices in the newspapers:—probably he might ascertain by application at the so-called Westminster Hospital School, at Charing Cross, or in Gower Street.

A HINT TO LECTURERS.

THE *Lancet* publishes what it calls a "student's number;" in which the announcements of the various lecturers are transferred from the wrapper to the pages of the journal, with remarks, laudatory or otherwise, bearing a relation to the number of times the advertisements may have been paid for, and other equally substantial reasons. On the present occasion, the prospectuses of two of the schools—viz. King's College and St. George's—are garbled, and disparaging remarks made upon them. Now it so happens that neither of these schools have sent any of their advertisements to the *Lancet*, and we learn that there is a positive (and we confess we think very absurd) order, at King's College, against doing so. We merely mention the above as a curious coincidence—not for a moment supposing that the circumstances are at all connected: we know the honesty of the Editor too well for that!

CLINICAL LECTURE ON ENCYSTED TUMORS,

Delivered at St. George's Hospital,

BY SIR B. C. BRODIE, BART.

IN this lecture I shall make some observations on the case of a little girl who was in one of the upper wards with a large encysted tumor, containing watery fluid, and occupying a considerable portion of the left hypochondrium. The following are briefly the notes of the case:—

"Harriet Copeland, æt. 9, was admitted on the 12th of March, with a firm elastic tumor in the left hypochondriac region, pushing forwards the integuments, and extending backwards, beneath the lower ribs to the left side of the spine. No pain was felt on pressure. The appearance of the neighbouring skin was perfectly natural, and the patient's general health was good. Her mother states that about twelve months ago the child had received a severe blow in the left side from her schoolmistress. The pain which immediately followed soon subsided; and the occurrence was forgotten until about three weeks before she was admitted into the hospital, when, in the act of running, she struck her side with much violence against a post. Great pain followed the accident; and on examining the part, her mother first discovered the tumor, in the situation above described. At this time it was equal in size to a hen's

egg, but it rapidly increased in growth, and it is now as large as an orange."

Having inquired into this little girl's case, I was led to believe that she had an encysted tumor in the abdominal cavity, and that it was probably connected with the liver. I determined, however, to keep her for some time in a state of quiet, in order that we might watch the undisturbed progress of the disease, and that I might be able to judge whether this opinion was correct. On the 30th of April the tumor had considerably increased in size, and presented to the fingers a distinct sense of fluctuation. I now punctured it with a small flat trochar, and drew off about eight ounces of a clear watery fluid, in which was found no coagulable matter. It will be unnecessary to occupy your time with the minute details of this case, the more so as they may be seen in my Clinical Book, to which you have all access. The principal facts may be thus briefly stated:—

After the operation, the patient vomited. Inflammation, beginning at the seat of the tumor, followed, and extended to the neighbouring parts. Bleeding, purging, and other antiphlogistic remedies, were of course employed. In spite of all, however, the belly became swollen, tympanitic, and tender. Shortly after a swelling, which was attended with considerable pain on pressure, shewed itself, occupying the place of the original tumor. On the 19th this had increased in size, and the fluctuation of fluid was perceptible in it; but in a few days more it had altogether disappeared, and pus mixed with feces came away from the bowels. On the 29th a membranous cyst, of which the parietes in their contracted state were of considerable thickness, was found in one of her evacuations. From that time the patient began to mend, and was soon convalescent.

The important parts, then, of this case, may be thus briefly summed up:—There was a tumor in the left hypochondriac region filled with fluid. The tumor was punctured. The fluid, when drawn off, resembled clear water, and was found to contain no coagulable matter, or so little as to be scarcely perceptible. Inflammation ensued. A swelling, having the character of an abscess, then formed, which soon disappeared, and disappeared exactly at the same time that a purulent discharge came away from the intestinal canal. From all these circumstances, conjoined with the final separation of the cyst, it would seem, that after the operation, the cyst suppurated, and that having discharged its contents through the bowels, it afterwards made its way into them by ulceration.

The opinion which I at first formed respecting the nature of this disease, was

in a great measure deduced from two cases which were under my care some years ago. I was consulted respecting a lady who had a considerable fluctuating tumor in the right hypochondrium. It was larger than the one of H. Copeland, but in every other respect was similar to it. The only symptoms which seemed to accompany it, were some slight pain in the side, and some difficulty of breathing, in consequence of the pressure which it made on the diaphragm. A most intelligent physician, who was in attendance, thought that there was an abscess in the liver; and the first appearance of the tumor was any thing but unfavourable to such a supposition; but, then, there were none of those severe constitutional symptoms with which abscess of the liver is usually accompanied. The tumor went on increasing in size, and at last I proposed that it should be punctured. Accordingly, this was done; and about three pints of a clear watery fluid were drawn off, containing no coagulable matter, and little animal matter of any kind. The edges of the wound were brought together with sticking plaster, and a bandage applied. After the operation, the patient was annoyed by a most violent and incessant cough, which, as it was attended with no constitutional symptoms, and with no other pulmonic symptoms, I was led to think depended either upon hysteria, or upon the sudden abstraction of pressure from the diaphragm, or on these two causes combined. In three weeks, whatever was its cause, the cough entirely left her. No pain was felt in the situation of the puncture. She got quite well, and to my certain knowledge continued well for at least the space of six years. Indeed, I have every reason to believe that she is so still. A few months afterwards, a little boy was admitted into the hospital with a tumor also in the right hypochondrium, smaller than the last, but in every other respect closely resembling it. I treated it in the same way, that is, by puncturing it with a trochar; and the clear watery fluid which came away was exactly similar to that which had been drawn off in the other case. No inflammation, nor any troublesome symptom, followed, and the boy left the hospital as cured. Whether he remained well for any length of time, or whether the disease returned, I cannot positively say; but it is most probable that, if it had returned, I should have known it.

I shall give my reasons presently for believing that these membranous cysts were connected with the liver. But similar cysts may exist elsewhere. They are not very uncommonly met with in the breast. Not that every encysted tumor of the breast is of this kind: far from it. Sometimes, on cutting into a mammary

encysted tumor, you find that the fluid, instead of being clear, like water, has the appearance of dark brown turbid serum, containing much coagulable matter. In these cases there is generally in addition to the cyst, more or less of solid substance, approaching to the character of a malignant disease: I do not mean that it is actually carcinoma; in fact, it is less liable to return after it has been removed than carcinoma, but still, if left to itself, it runs the course of a malignant tumor, and is incurable, except by operation. The species, however, of mammary encysted tumor which I first mentioned, in which there is merely a thin cyst, containing nearly pure water, is altogether independent of malignant disease. If after puncturing one of these cysts, and letting out the fluid which it contains, you do nothing more, you will find that when the wound heals, the cyst again fills. But if you dissect it out, taking great care to leave none of the cyst behind, there will be no return of the disease. Sometimes stimulating applications will succeed in effecting a speedy and a permanent cure, so that an operation may be avoided. I have known this to happen in more than one instance.

A lady, having one of these encysted tumors of the breast, consulted me. It was as large as a small orange. I punctured it, and drew off a considerable quantity of clear watery fluid. The wound healed up, and the cyst again filled. I then advised her to have the tumor removed by excision. She made no objection, but requested me, for certain reasons, to defer the operation for a fortnight or three weeks. This being settled, I advised her in the mean time to apply to the breast an embrocation, which was much used by Sir Everard Home, and, as I believe, before him by Mr. Pott, and which I have found of so much service, that I will give you the prescription. It consists of proof spirit and camphorated spirit, of each ʒiiss. ; Goulard's extract, ʒj. A flannel is to be dipped in this, and to be applied to the part several times daily, being allowed to remain there. Well, then, to return to my case: this treatment was followed for three weeks, at the end of which time the lady said that she was quite prepared for the operation. But now, on examining the breast, I found that the tumor had altogether disappeared. This case is the more interesting, inasmuch as the tumor was of a large size. Exactly the same thing happened in another case of mammary encysted tumor for which I proposed the operation, and which differed from the last only in being somewhat smaller in size. I do not say that in such cases the embrocation will always succeed. But it

never does harm, and has succeeded quite often enough to entitle it to a fair trial before resorting to excision. Probably some other stimulating applications would answer the same purpose.

Tumors of the same kind occur in connexion with the testicle. The encysted hydrocele of the testicle, which is sometimes erroneously supposed to be a double or lobulated testicle, consists of nothing but one of these cysts situated between the inner layer of the tunica vaginalis and the fibrous membrane of the tunica albuginea. A similar cyst occurs every now and then in the epididymis, between its convoluted tube and the tunica vaginalis, by which it is invested. Then, again, it is one of the same cysts which constitutes the encysted hydrocele of the cord, in which disease the tumor is extremely loose and moveable; so much so, that it may, when of a moderate size, be pushed up through the external ring, not into the abdomen, but behind the tendon of the external oblique muscle, and hence it is sometimes confounded by an inexperienced surgeon with inguinal hernia. In all such cases, the fluid which the cysts contain, is sufficiently characteristic of their nature. It is a clear watery fluid, the cases in which it is serum, like the fluid of a genuine hydrocele, being very rare indeed. In examining bodies after death, my attention has been often attracted by small membranous cysts situated between the glandular structure of the liver and its peritoneal covering. Sometimes I have seen them as large as a walnut, at other times as large as an orange; but there is no reason why they should not attain to any magnitude. Now, as we know that these tumors do occur in connexion with the liver; that they occur but very rarely indeed in the spleen, and as far as I know, still more rarely in the other abdominal viscera; and as the position of this tumor, in each of the cases which I have described, made its attachment to the liver by no means improbable;—I suppose this was the real seat of the disease; and I think that you cannot doubt this to be a legitimate conclusion.

In the two cases of this kind which first fell under my observation, no bad symptoms followed the operation. In this last case, however, inflammation and suppuration were the consequence of it. The cyst seems to have contracted adhesions to the colon, and having discharged its contents into it, escaped, by ulcerating its way probably into the transverse arch.

As soon as I saw that the tumor had returned, my determination was to make an opening into it, and to give exit to the confined pus; but, while I was waiting for

a good opportunity of doing this, a purulent evacuation from the bowels took place, and of course it was then too late for what I had intended.

There can be no doubt of the propriety of puncturing cysts of this kind, when they have attained such a magnitude as to be inconvenient from their bulk. There is no reason for puncturing them sooner, and there are good reasons against it. The object of the operation is simply to draw off the watery contents of the cyst, and if these should become again collected, the puncture may be repeated. In Copeland's case, however, there can be no necessity for any second operation. The cyst having suppurated, and afterwards sloughed, there must be a radical cure of the disease: but we must acknowledge that this advantage has not been obtained without the patient having incurred a certain degree of risk, which we should endeavour to avoid in future. In the two former cases I merely drew off the water, without taking any great pains to empty the cyst completely. In this last I now think that I was over anxious to obtain this last object; and to the pressure which was in consequence made on the cyst, while the canula remained in it, I cannot but, in great measure, attribute the inflammation, suppuration, and sloughing of the cyst, which followed.

You will perhaps inquire, for what reason did I puncture the cyst with a trochar instead of using a lancet? The answer is plain enough. The cyst is more readily emptied by means of a canula than without it; and if there were no adhesions of the cyst to the peritoneum lining the abdominal muscles, and you were to puncture it with a lancet, the fluid would escape into the cavity of the abdomen,—an evil which must be avoided when the operation is performed with a trochar.

GLASGOW EYE INFIRMARY.

Melanosis and Ossification of the Eye.

JOHN TAYLOR, æt. 41, admitted 13th May, 1831. About nine years ago, while in America, the vision of the left eye became dim, and was soon lost entirely. At present the bulb of the eye is shrunk and knobbed. There are still traces of cornea, behind which is a white substance, apparently the lens. Adhering to the bulb of the eye, at its nasal side, there is a prominent tumor larger than a pea, smooth on the surface, covered by the conjunctiva, and firmly attached to the bulb: pressure on the tumor occasions pain. Is troubled with uneasy feelings in the

forehead, especially over the left brow. There is inversion of right lower lid, and the consequent friction of the eyelashes seems to excite irritation in the tumor. Vision of right eye good.

May 19th.—The inversion of lower lid having been cured by operation, the tumor was this day removed with the seissors; its contents were dark-coloured and of considerable consistence, so that the tumor did not collapse.

May 23d.—A greyish fungus protruded in the situation of the tumor.

30th.—Eye free from pain; tumor stationary.

The patient was advised to have his eye extirpated; but unwilling to submit to the operation, he discontinued his attendance at the Infirmary. He however returned on the 5th August, and signified his wish to have the operation performed.

August 6th.—The nasal half of left eye is occupied by a dark-coloured soft tumor, about the size of a filbert, the anterior surface of which is marked with a

stellated sear, the result of the former operation. The tumor, he says, is rapidly growing; considerable pain on left side of head down to the neck, preventing sleep. Stomach very irritable; bowels rather loose.

7th.—Left eye extirpated by Dr. Mackenzie. A small cut having been accidentally made into the edge of each lid, those were brought together each by a stitch. Nothing was introduced into the orbit, but the lids were covered with a piece of simple dressing and a roller.

On examination, the whole eye was found atrophic. The cornea, as could be seen before the operation, was not more than two Parisian lines in diameter; it was, however, clear, so that the opaque lens could be seen through it. The optic nerve was much reduced in thickness;

indeed, nothing but the neurilemma of the fibrils seemed to be left, all the medullary matter being absorbed. The tumor, which was about five or six Parisian lines in diameter, protruded through an opening in the sclerotic, on the nasal side of the dwarfish cornea. It was covered externally by a production of the conjunctiva. On making a section of the tumor, it was found to consist of a light bistre-coloured tissue, nearly of the consistence of muscle, which, when torn, indicated a fibrous structure. The section through the tumor being continued through the eye ball, this was found to have undergone extensive disorganization. There were some remains of the choroid and annulus albidus, but the retina was substituted by a bony lamina, and the neurilemma, which was all that remained of the optic nerve, at the place where the latter joins with the retina, had several earthy deposits in it; the lens was entirely converted into an earthy matter, which affected a laminar arrangement; the capsule was very tough. There was no trace of iris or posterior chamber; the anterior chamber was very small. All the rest of the interior of the eye was filled by a melanotic mass, of pappy consistence, from which the tumor appeared to rise. There was besides this, towards the inner side and back part of the eye, a small mass of a reddish-white substance, like brain, and a small quantity of a soft dark-red matter. In the interior of the tumor some red matter was also observed, surrounding and isolating a nodule of the bistre-coloured tissue from the rest of the mass.

The pappy melanotic matter contained in the interior of the eye, being examined with a microscope, was observed to be composed of black particles of no definite form; interspersed among which were some minute crystals, of a rhomboidal shape. The tissue composing the tumor (which, as has been said, was somewhat fibrous), on examination with the microscope was seen to consist of flattened globules, considerably larger than those of the blood, united together in fibres by a delicate cellular tissue. The most of the globules were light-coloured, but there were interspersed among them a great number of dark coloured bodies, which appeared to be globules containing in their substance black particles. The brain-like and dark-red matters were also composed of globules, but very few black bodies were observed among them.

August 11th.—No pain since the operation; rests well in the night. Stitches removed.

20th.—Quite free from the pain felt before removal of the eye.—Dismissed.

ACADEMY OF SCIENCES, PARIS.

Monday, Sept. 1, 1834.

THE SPHYGMOMETER.

M. MAGENDIE read a report, drawn up by himself and M. Serres, on an instrument called the *sphygmometer*, intended not only to measure the pulse (as its name implies), but to render visible those several varieties of the circulation which are usually observed by the sense of touch. If this contrivance (said M. Magendie) were really competent to set before the eye the principal phenomena of the arterial circulation,—if it could supply the means of measuring, and of course of expressing precisely, by signs similar to those by which variations of temperature, for example, are denoted—then would the sphygmometer, as it is called, prove an important acquisition in medicine; for even the most practised physician, no matter how delicate his sense of touch may be, is far from possessing, in his investigations by the pulse, a degree of certainty like that which results from the use of the thermometer. But it requires at least as much practice to learn the proper use of this instrument, as it does to become acquainted with the ordinary indications of the pulse: nor are the results in any degree more exact. We have taken two persons, both familiar with the sphygmometer, and causing each successively to apply it to the radial artery of one and the same individual, we have requested them to write down separately what they ascertained by the instrument: the results, as stated by the parties, have been materially different (*sensiblement divergents*).

The inventors of the sphygmometer, like most other inventors, promise and predict great things, as about to spring from their contrivance: they state, on the faith of facts which your reporters have not been able to verify, that the indications afforded by this instrument will furnish certain signs by which medical men may detect the presence of several maladies whose diagnosis is at present obscure. While we are ready to admit that the sphygmometer is an ingenious thing, and not unworthy of trial in the hands of physicians, we can by no means partake of the sanguine hope of the authors; we moreover think, that if MM. Herisson and P. Garnier intend to reach the object at which they aim, they must, by some modification in the apparatus, render its use

more simple, and free from the necessity of conjectural approximations.

In conclusion, the reporters propose that the thanks of the Academy be given to MM. Herisson and Garnier, for their communication, and that those gentlemen be requested to simplify their instrument, if possible, so that the fidelity of its indications may no longer depend, as at present it does, on the cleverness and nice precautions of the observer.—Adopted.

Dr. Herisson has sent us his pamphlet on the *Sphygmometer*, from which we had the engraving in the opposite column copied, on a reduced scale. D represents a graduated capillary tube, in which the ascent of the mercury at each stroke of the pulse is observed. The lower part, or bowl, of the instrument is to be applied to the artery: and C is a stop-cock, which is closed till every thing is prepared.

THE ITCH INSECT.

THE detection of this minute animal has created quite a sensation among the *savans* of Paris. M. Renucci, a student of the Hôtel Dieu, has been the first to put beyond a doubt the existence of the gemine *Acarus scabiei*: he has in consequence, beside the credit due to him for his success, netted 300 francs, which M. Lugol, a few years ago, offered for, or rather wagered against, the discovery of the insect. All the descriptions hitherto given of the *A. scabiei*, by Bonomo, De Geer, Baker, Alibert, and others, have been inaccurate and fanciful: they would have better served to represent the mite of cheese. The true *A. scabiei*, like the mole, has its forelegs strongly developed, while its hind quarters are comparatively feeble; it is thus enabled to burrow under the cuticle, and to make a road for itself as it proceeds. Plans and drawings of the animal, on a greatly magnified scale, have been laid before the Institute by M. Beaudé; and M. Raspail, whose skill in exploring minute objects is so celebrated, is engaged with his microscope in procuring further details.

We learn from a letter addressed by M. Renucci to the Academy of Sciences, that in the year 1825, while he was attending his brother's practice in Corsica, he often had an opportunity of observing the method pursued by women of that country in extracting the acarus, usually called by them the *pedicello*. M. R., aware that the existence of the insect was denied by many eminent naturalists and physicians on the Continent, took pains to ascertain the signs of its presence; he devoted a good

deal of study to the subject, and thus was enabled recently to point out the true *A. scabiei* to M. Alibert, at the Hôpital St. Louis.

The proper mode of proceeding for the purpose, is to examine the vesicles of an itch patient newly infected, and not yet under cure. At the base of any one of them will be found certain little furrows, going off in different directions, some towards the summit of the vesicle, others running round it, and others again prolonged beneath the neighbouring skin. Observe the furrow which diverges most from the vesicle, and at its extremity will in general be detected a white point, visible with the naked eye. This white point, where the cuticle is slightly elevated, corresponds to the posterior part of the insect. In warm countries, says M. Renucci, I have further been able to discern the head, which is brownish. Whenever we can distinguish two such points, we may be almost sure of finding the insect. In order to extract it, we must pierce the cuticle with a needle, at about the distance of half a line from the white point, when, by gently dividing the epidermis upwards, the acarus is laid bare, and easily removed.

It is not rare to find it at the base of the vesicle; sometimes it is even found on the sides; but very rarely, or perhaps never, on the top. Most likely it was owing to this circumstance that many of those who sought the acarus scabiei with such industry in the vesicle or its fluid, were induced, from their want of success, to deny its existence altogether. The figure given by De Geer is, according to M. Renucci, rather that of the itch insect of the horse, than of the *A. scabiei* of man.

But after all, says a writer in the *Journal Hebdomadaire*, it does not follow that this insect, the presence of which we have ourselves witnessed, is the real cause of the itch. It still remains to be seen whether there may not be genuine itch without an insect—whether the acarus now detected be the same in all patients affected with scabies—and whether it be not found in other animals, or even in animal or animalized substances, placed in circumstances favourable to the propagation of insects, such as heat and humidity.

CHOLERA IN A MARE.

By MR. E. C. BULL, V.S. HUNTINGDON.

I WAS called at 5 P.M. on the 15th of the present month, to see a mare, five years old, with a foal of six months, belonging to Mr. Knighton of Huntingdon. She was perfectly well in the morning; but I found

her at the time stated very much tucked up, voiding copious watery stools, of a fetid smell and dark colour; the pulse at the submaxillary artery quick and very feeble; extremities very cold, the nose and ears particularly so; the eyes very dull; the breathing much oppressed; and there seemed to be suppression of urine. I bled her, and obtained with difficulty three quarts of dark treacley blood. I gave her ℥j. of laudanum and ℥j. of spt. nitrous ether, and administered an injection of laudanum and starch.

Seven o'clock.—Much the same. I attempted to bleed her again, but could only obtain half a cupful. I repeated the injection, and blistered the belly largely.

On the morning of the 16th she was much worse. I repeated the injection, allowed her to drink five quarts of warm water, and blistered the legs.

Eleven o'clock A.M.—Purging stopped; pulse not to be felt; breathing very difficult; tongue blue, cold, clammy; the lips also very blue.

One o'clock P.M.—She fell down as if cramped; voided more faeces, of a much lighter colour, frothy, and with a putrid smell; and there was much twitching of the legs. This gradually subsided, and about three o'clock she died very calm.

Post-mortem examination.—Bowels much distended with flatus, and congested in several places; as also was the bladder, and especially the lungs, which were gorged with blood; but there was nothing like inflammation of them, or solidification, or effusion.—*Veterinarian.*

HYDROPHOBIA COMMUNICATED

BY A COW.

It has been asserted by some who hold a high rank both in the veterinary and medical world, that rabies can be communicated by those animals only who use their teeth as weapons of offence. We have often wondered at the unhesitating and dogmatical way in which this assertion is made, for we are ignorant of any theoretic principle on which it could be possibly grounded; it is contrary to occasional facts, well known to all who have paid attention to the subject; and it is likely to lead to dangerous and fatal neglect of proper precautionary means.

A late number of the *Journal Théorique* has added another to the cases of death succeeding to inoculation with saliva from a rabid ruminant, and also of the fearful period during which the virus may remain inert in the frame.

A cow, in the department of Jura, was bitten by a dog affected with rabies. Some

time afterwards she became dull, and refused all kinds of food. She approached to some water which was offered to her, and made repeated but fruitless efforts to swallow it. A woman that had the care of her imagined that some foreign body was lodged in the pharynx, and prevented the animal from swallowing; and she thrust her hand into the mouth of the beast, and to the very back part of it, but found nothing. In doing this her hand was slightly scratched by one of the teeth of the animal. It was soon afterwards sufficiently plain that the cow was rabid, and she was destroyed by order from the magistrates.

A year afterwards the woman began to have frightful dreams, in which she thought that she was pursued by two enraged animals, the cow, and the dog by which it had been bitten. She had dread of water, and she died of rabies in a state of horrible suffering, attended by circumstances peculiarly lamentable.—*Ibid.*

MIDWIFERY SCHOOL AT GUY'S HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

HAVING read a pamphlet by Dr. Blundell, calculated to produce an erroneous impression, I am anxious to prevent such a result by a very brief statement of facts.

Dr. Blundell has certainly retired from Guy's, and there are connected with his retirement some circumstances requiring an explanation, which his letter does not afford. It must be supposed from the statement, "that the gentleman whom the Treasurer seemed desirous to patronize," and the insertion of whose name as a joint obstetric lecturer appears to have been the grave indignity which the Doctor could not brook, was a nominee, or protégée, of the Treasurer, unknown, or nearly so, to Dr. Blundell.

The entire reverse of this is the fact. Nine years ago negotiations were entered into between Dr. Blundell and myself, without the Treasurer's knowledge, the object of which was my succeeding to the obstetric chair; a large pecuniary consideration being required by Dr. Blundell. But as it was intimated to me that the Treasurer would not for a moment listen to, or allow, any arrangement founded on a pecuniary basis, I abandoned the idea, but continued my obstetric pursuits at the hospital. In 1829-30, in consequence of new arrangements which then took place, I was requested by Dr. Blundell to give

clinical instructions to his pupils. It had been recommended by the Doctor to have a lying-in ward; but instead of it, the present Hospital Lying-in Charity was established, and cases of uterine disease were admitted into a part of the hospital appropriated to that purpose. I then received a communication from Dr. Blundell, requesting that, as his duties were increased, and his health uncertain, I would officiate as his obstetric assistant. It was not till this period that I had the pleasure of being personally known to the Treasurer. I gave the clinical lectures for two or three seasons; I saw and treated nearly all the cases in the obstetric ward; I had the entire charge of the Hospital Lying-in Charity, and of the obstetric out-patients; and I gave forty out of the forty-three midwifery lectures in the spring course of 1831, having been solicited to do all this by Dr. Blundell himself.

Surely, then, the circumstance of my name being associated as colleague (for it had been so already as obstetric assistant), is no justification of the indignation he expresses. Can it be deemed extraordinary, after what I had done, that I should express a strong wish that my name should be included in the lecture papers, as colleague; so that, in the event of renewed illness, and his requiring a large share of help from me, I should appear before the class on the proper footing, and prevent the doctor's inability being regarded as a breach of faith, either on his own part or that of the school?

If Dr. Blundell has retired from Guy's, it is (to use his own words) because "sic jubeo, sic volo, stet pro ratione voluntas."

It appears, by his own statement, that he might have resumed the chair, if he had not considered it "redolent and reeking with the indignity that stained it." I may be allowed, perhaps, to express my surprise and regret that this indignity was supposed by him to consist in my being called upon to act as his colleague, instead of his representative; in which situation I had reason to believe, from the close attention and numbers of the class, that my services had given satisfaction. Dr. Blundell, however, evinced his prompt determination to retire, by the immediate removal of his museum; a step unattended by inconvenience, as the rich museum of the hospital is well provided in the obstetric department.

I may here, perhaps, just observe that Dr. Blundell was introduced to the Treasurer by his respected predecessor, Dr. Haughton, in the same manner as I have been by himself; but it is somewhat singular that he has not alluded to the exertions of his honoured relative, from

whom he received a class greater in number than it has since been. The present high repute of the hospital and school, in all its departments, is too well known to call forth any remarks from me. I trust I have shewn that Dr. B.'s statement, "that he had not introduced the gentleman whom the Treasurer thought right to patronize," is not correct.

I am, sir,
Your humble servant,
SAMUEL ASHWELL.

13, Devonshire Square,
Oct. 2, 1834.

COLLEGE OF PHYSICIANS.

THE annual appointment of officers took place last Tuesday, when Sir Henry Hallford was re-elected President; Drs. Cholmeley, Royton, Roget, and Roots, Censors; Dr. Turner, Treasurer; and Dr. Francis Hawkins, Registrar.

COLLEGE OF SURGEONS.

Members admitted in the Month of September,
1834.

Thomas Dixon, Preston.
George Crutch, Londwater, Bucks.
Wm. R. Williams, Caernarvon.
James A. Wills, Brompton, Middlesex.
Wm. T. Tyson, Canterbury.
Samuel Maberley, Webb-Street, Borough.
Frederick C. Gray, Alton, Hants.
Francis Anderson, Belfast.
John Griffin.
Peter G. Heatley, Manchester.
James Jeffares, Dublin.
Wm. Phillips, Brocton Grange, Salop.
Benjamin Blower, Shrewsbury.
Lewis Davies, Llandiloe.
Edward H. Moxon, Rochester.
John L. Lucas, Northampton.
Simon Murchison, Bath.
Joseph Schofield, Aston-under-Line.
Charles H. Higgins.
John Smith, Wigton.
Bellas Moses, Brompton, Cumberland.
William Getty, Liverpool.
Alfred Morson.
Milward Pagson, Southampton-Street, Fitzroy-Square.
Charles Leah, Penzance.
Charles L. Parker, Long Acre.
James M. Dermott, Newmarket, county of Clare.

ST. THOMAS'S HOSPITAL.

DR. BURTON was, on Monday last, elected Physician to St. Thomas's Hospital, in the room of Dr. Elliotson, resigned.

LECTURES

ON

DISEASES OF THE CHEST,

In the course of which the Application of

PERCUSSION AND AUSCULTATION

ARE FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE II.

THEORY OF THE SIGNS OF DISEASES
OF THE LUNGS—(continued.)

MECHANISM OF THE CHEST.

WE now proceed to the consideration of a subject immediately connected with that which we discussed in the last lecture; namely, the examination of the structure by which the important organs of the lungs and the heart are protected, and of the mechanism by which that structure adapts itself to the constantly-varying capacities of the lungs.

When we reflect upon the great importance of the functions performed by the lungs and the heart, so important that their cessation for a very short period, indeed, would be productive of death, we must naturally suppose that there should be some protecting envelope or case for them. When we recollect, also, that the lung, particularly, is constantly varying in its capacity; that at one moment it enlarges, that at the next it diminishes in performing the acts of inspiration and expiration, we see that it is necessary that the case which protects it, should also have the power of dilating and contracting to follow these movements. We find, therefore, that the double function of protection and mobility is beautifully effected by an organization of bones, muscles, and cartilages, known under the appellation of *the chest*.

Before we proceed to explain the func-

tions which the chest performs, we must first take a glance at its structure. The gentlemen around me must be generally acquainted with that structure, but still it is requisite that we should take a general view of the subject.

Position and form of the chest.—As to the position of the chest, it is placed at the upper part of the trunk, between the cavities of the cranium and abdomen. Its form is that of a cone, whose apex is above, and truncated, and whose base is below, large and open; at least it should be so in a well-formed subject: if, however, you were to examine the chest in a living individual, you would form a very false notion of its shape. It would then appear that the base of the cone was above, and the apex below. This arises from the length of the clavicles, and from the shoulders, which give a breadth at the upper part, and from the narrowness of the waist below: in some persons, particularly in females who have acquired the unfortunate habit of binding the waist too much, this is still more apparent.

Structure of the chest.—We will now examine the structure of the chest. In the first place, we have it formed anteriorly of the sternum and costal cartilages; posteriorly, of the vertebral column, particularly of the bodies of the vertebrae; and laterally, of the ribs.

Sternum.—The sternum consists in early life of five bones, and on its anterior surface there are four transverse lines indicating their former separation. Anteriorly, it is slightly convex, and covered merely by the aponeurotic expansion of the sterno-mastoid, and pectoral muscles, and by the skin; posteriorly, the bone is a little concave. At the superior portion there are articulating surfaces for the clavicles, and also for the first ribs. The inferior portion is terminated by a point, called the ensiform or xiphoid cartilage. There are, laterally, seven depressions for the seven corresponding ribs.

Ribs.—The ribs are twelve in number on each side: the seven superior are called thoracic or true ribs, and are articulated by the intermedium of cartilage directly to the sternum; the five inferior are termed false or abdominal ribs, each being articulated anteriorly to the one above it by cartilage, and thus indirectly with the sternum. The two last ribs have merely cartilaginous tips, and are called the loose or floating ribs. The ribs are flattened in front, and gradually become more rounded behind. Their length is various; the first is the shortest; the second is nearly double the length of the first: they progressively increase to the eighth, and then gradually diminish until the last. Their breadth also varies: the first may, perhaps, be considered the broadest, the second is somewhat less, and we find a gradual diminution as we descend.

Direction of ribs.—The next point to which I shall call your attention, is the direction of the ribs, and this is a matter of considerable importance in relation to their movements. The first rib arises nearly at a right angle with the vertebral column, and the acuteness of the angle increases as we descend from the first, so that each rib being inclined outwards and downwards increases also in the obliquity of its course, and the result of the particular direction is, to give to the whole lateral parts of the chest a general inclination downwards and forwards. Each of the ribs taken separately presents a twisted form, the point of torsion being at its angle. Anatomists describe each rib as having a posterior or vertebral head, a cartilaginous end, and a body. The head of the bone is articulated with the sides of the bodies of the two corresponding vertebrae, with the exception of the first, eleventh, and twelfth, which are each connected to a single vertebra. The head of the rib is supported by a short neck. External to the neck, there is a process called a tubercle, which has an articulating surface, and is connected with the transverse process of the vertebra below it. This is the case with all the ribs, except the first and the two last. The bone then becomes somewhat flattened, and is bounded by an angular projection, which is removed farther and farther from the tubercle as we descend towards the last rib: this is called the angle, and is, as I have already said, the point of torsion or twisting of the bone. The sternal extremity is hollowed out and thin, for the insertion of the cartilage. The external surfaces of the ribs are convex, and covered by muscles and skin; their internal surfaces are concave, and lined by the pleura. They have a superior and inferior edge. Observe the grooves in the inferior edges for the intercostal arteries,

arteries which might possibly, but not probably, be wounded in the operation of paracentesis thoracis.

Generalities; external surface of the chest.—Having considered the chest in its separate bones, let us now examine it generally. In the first place, it has an external and an internal surface; a superior and an inferior circumference. The external surface may be considered in four points of view, in its posterior, anterior, and two lateral regions. In the posterior region, you see [referring to a skeleton] the spinous processes of the dorsal vertebrae, and the gutter on each side of them; the transverse processes of the vertebrae; the tubercles of the ribs; the spaces between the tubercles and angles, enlarging as we descend, and the angles forming an oblique line from above downwards and outwards. On examining the chest anteriorly, we first notice the sternum in its centre, and on each side there are the cartilages of the ribs. These cartilages gradually enlarge as we descend, and form an oblique line from above downwards and outwards. The lateral regions are convex, and formed by the bodies of the ribs.

Internal surface of the chest.—Internally, the chest is to be considered in relation to the same positions as externally; that is, the posterior, anterior, and the two lateral regions. Posteriorly, we have the convex surface of the bodies of the dorsal vertebrae. Observe that the dorsal vertebrae decrease in size from the first to the fourth, by which the antero-posterior diameter is there so much increased: the vertebrae then gradually enlarge to the twelfth. In this region, too, you perceive the articulation of the heads of the ribs. Anteriorly, there is the posterior surface of the sternum corresponding to the anterior mediastinum and the cartilages of the ribs. The lateral region presents a concave surface, covered by the pleura.

Superior and inferior circumference of the chest.—The superior circumference is formed by the sternum, by the first rib on each side, with its cartilage, and by the anterior part of the body of the first dorsal vertebra. The inferior circumference is bounded by the last dorsal vertebra, by the last or floating ribs, by the successive edges of all the false ribs, and by the xiphoid cartilage.

Such is a general view of the anatomy of the bones of the chest.

FUNCTIONS OF THE CHEST.

Protection.—We will now proceed to the functions of the chest, and the first to which we must advert is the protection it affords to the thoracic viscera. Let us consider this subject in relation to the regions we have just described. We will suppose the case of a force being directed

against each of these parts. Posteriorly, great protection is afforded to the chest by the spinous processes and bodies of the vertebræ, and also by the large mass of muscles of the back. Two modes of protection are afforded by the upper part of the lateral regions, one only by the lower: thus, the seven superior ribs, arched, and consequently of the best form to afford a resistance, have each two abutments, the one vertebral, and the other, by the intermedium of a cartilage, sternal. When a blow is expected, a strong inspiration is made, the ribs are then carried outwards, their extremities become more fixed, and their arches are rendered firmer, and the force is received with a *resistance*; but when the blow is unexpected, when there has not been time to effect a deep inspiration, the whole chest *yields* by its admirable elasticity, and the force of the shock is disseminated and lost over its whole surface, often with perfect impunity to its structure: but the five inferior ribs being so indirectly connected with the sternum, cannot have their anterior extremity fixed in the same firm manner as the seven superior by the deepest inspiration; they protect not, therefore, by *resisting*, but by *yielding*.

The anterior region affords also two modes of protection; namely, by resistance and by yielding: the sternum is slightly convex or arched: its two extremities are moveable, the inferior most so; and when a strong inspiration is made, the sternum is elevated, particularly at its xiphoid portion, and the bone is thus firmly fixed, and *resists* a force applied to it; if, however, that force be unexpected, it *yields*, and the shock is diffused over the chest, and lost.

An illustration of the two modes in which a force may be received is, I dare say, familiar to most of you: thus, in catching a ball, struck, I will suppose, from a bat, a tyro at the game will advance his hand to receive it, and will suffer according to the resistance he gives; while the experienced player allows his hand and arm to yield, and the force of the ball is diffused over the whole of his body.

Movements.—The next important function which the chest has to perform relates to its movements. In order to understand the movements of the chest, we must first study it in its various diameters: these are three. In the first place, we drop a line perpendicularly at the upper aperture of the chest, midway between the sternum and vertebral column to the diaphragm, and we call that the *perpendicular* or *diaphragmatic* diameter. We then take the measurement from the posterior part of the sternum to the anterior part of the bodies of the dorsal vertebræ, and we term that the *antero-posterior* or *sterno-vertebral* diameter. We then measure the chest

across from rib to rib, and denominate that the *transverse* or *costal* diameter.

In consequence of the conoid form of the chest and of the oblique direction of the diaphragm, which is the base of the cone, these diameters vary in different parts: thus, the perpendicular is greater at the posterior portion of the chest, and shorter as we advance towards the sternum; the antero-posterior is longest from the xiphoid cartilage to its opposite dorsal vertebra, and shortest from the first bone of the sternum to the first dorsal vertebra; the transverse is broadest at the lower part of the thorax, and becomes gradually narrower as we ascend.—[Shewn by the skeleton and diagrams.]

Movement of inspiration.—There are two movements of the chest, the one by which we inspire a certain quantity of air, and consequently increase the capacity of the lung; and the other by which we expire, and therefore diminish the capacity of the organ. Every time we inspire, it is necessary that the chest should enlarge in one or other of its diameters, in proportion to the quantity of air inhaled: this is self-evident. What, then, is the diameter which you would, *à priori*, suppose would first increase? Of course, where the resistance is the least, and that is the diaphragmatic. In the act of expiration, the diaphragm is convex towards the lung and concave below; but in proportion to the quantity of air inspired, it descends and presses the abdominal viscera before it, and this increase in the capacity of the chest is sufficient for the ordinary inspirations in a healthy person; indeed, in old age, when the ribs become more fixed, the respiration is carried on alone by the diaphragm. When, however, the respiration becomes difficult, it is then necessary that all the diameters of the chest should be increased to their full extent: to understand this, let us suppose a case of extreme dyspnoea, as that arising from severe peripneumonia; on observing the patient, you will see that he is seated in nearly an upright posture, with his head thrown back, and his arms widely extended.

The head and neck are directed backwards, and are firmly fixed by the action of the muscles arising from the back, and inserted into the occipital bone: these parts becoming thus firmly fixed, the *sterno-cleido-mastoidei* act from them upon the sternum and clavicles, and draw the chest directly upwards. The clavicles being thus rendered firm, the *subclavii* muscles passing from them to the first ribs, elevate those ribs, and render them fixed points also: but, you are aware, that these ribs are not only elevated by the *subclavii*, they are still more powerfully so by the *scaleni*.

The first ribs being thus fixed, the second

are elevated and fixed also by the action of the double layer of the intercostal muscles, the fibres of which decussate each other, so that the action of one series would be to elevate the second ribs *obliquely* upwards; but the result of their united actions would be to draw them *directly* upwards (diagram); the second ribs being thus fixed, the third are elevated in the same manner by their intercostals, and so on to the last, each rib becoming alternately a moveable and a fixed point.

The whole of the ribs become thus elevated; but as they are directed obliquely downwards towards the median line; as the intercostal spaces, particularly of the false ribs, are wider anteriorly than posteriorly; and as these latter ribs are more moveable from these circumstances, and from their greater length and mode of insertion of their cartilages, so the sternal extremities of them all, but particularly of the abdominal, are elevated more than their vertebral, and their bodies are consequently thrown outwards. You have only to place your hands on the sides of the thorax in making a deep inspiration, and you will distinctly feel this. If the ribs are thrown outwards, the transverse diameter must be increased in proportion.

The *antero-posterior* diameter is enlarged as a necessary consequence of the elevation of the ribs; for, at the moment of that elevation, the sternum is pushed upwards, particularly by the cartilages of the false ribs; consequently the space between that bone and the bodies of the dorsal vertebrae must be augmented.

I have stated to you that the arms are also extended in extreme cases of dyspnoea: the superior extremities are thrown out, at acute angles, from the body, or are elevated above the head, to become fixed points, from which the ribs may be acted upon, and drawn outwards, to increase the transverse diameter of the chest. Thus, the pectoralis major being connected with the outer edge of the bicipital groove of the humerus, spreads broadly upon the upper parietes of the thorax, and acts upon the cartilages of the true ribs; the pectoralis minor, attached to the coracoid process of the scapula, elevates obliquely upwards the second, third, and fourth ribs; and finally, the serratus magnus, passing from the inside of the base of the scapula, and fixed by nine digitations into so many of the corresponding upper ribs, most powerfully draws them directly outwards, the scapula at the same time being fixed by the action of the trapezius, rhomboidens, and levator-anguli scapulae.

You may see that, by a beautiful compensation, the lower ribs, from their greater length of cartilage, and from their greater obliquity of course, are by far the most easily moved, and have therefore fewer

muscles to effect their movements; whilst the upper or thoracic ribs, from their greater fixation, have a number of powerful muscles to act upon them.

Varieties of dyspnoea.—Authors have made several varieties of dyspnoea, which I shall now notice. We have first what is called *abdominal* respiration, by which we mean the moving of the abdomen to a great extent, while the chest is immovable. When any cause prevents the extension of the transverse or the antero-posterior diameters, then the perpendicular diameter alone is susceptible of increase. Suppose the ease of a patient labouring under a violent attack of pleuritis, every time he attempts to expand the chest by increasing the transverse diameter, he presses the lungs against the inflamed part: he endeavours to avoid this by breathing by the diaphragm alone. Suppose, on the other hand, there be a difficulty of moving the diaphragm, as in peritonitis, in that case every time the perpendicular diameter is increased, the viscera are pressed against the inflamed part, and the pain is aggravated: the patient therefore tries, by elevating the chest, to increase the antero-posterior and transverse diameters only. In cases also of ascites, or pregnancy, or large tumors in the abdominal cavity, the perpendicular diameter is increased with difficulty, in consequence of the mechanical obstruction to the descent of the diaphragm: patients then breathe principally by elevating the chest. This is called *thoracic respiration*.

We have respiration which is called *complete* or *incomplete*. It sometimes happens that there is an effusion of fluid in large quantity into the cavity of one or other of the pleura, in consequence of which the lung becomes compressed. It cannot dilate, and the ribs do not move on that side, though they are active on the other, and hence the term *incomplete respiration*.

We have also *equal* and *unequal* respiration. These terms have merely a reference to time: thus, the inspiration may be shorter than the expiration. In acute pleuritis, the inspiration is short, and the expiration long.

Sometimes we meet with the expression *frequent*, or *slow*, respiration; but these words do not require any definition.

We have also *high* and *sublime* respiration. This occurs in extreme cases, where the patient endeavours to increase the diameters in every way.

There is another kind of respiration, denominated *orthopnoea*, by which we mean that the patient is enabled to breathe only in an upright posture.

Movement of expiration.—The act of expiration is performed in the healthy state by the diminution of the perpendicular dia-

meter of the chest, produced by the elevation of the diaphragm; but when we have a forced expiration, then all the diameters are diminished: this will be best understood by explaining the mechanism by which coughing is effected.

Forced expiration—cough.—A cough is commonly an effort of nature to remove some cause obstructing the passage of the air into the lungs: thus, the tracheal and bronchial mucus, if not absorbed or evaporated in proportion to its secretion, as in catarrh, accumulates, obstructs the air-passages, and we cough, to remove the obstruction. In old catarrhal persons, the power of coughing is often lost, and they become suffocated. Persons dying of other diseases lose this power, and the mucus accumulates, and the well-known and fatal tracheal rhoncus, or rattling sound, is then heard. Other obstructing causes may exist in the lungs; as, the matter of abscesses, of gangrene, of softening tubercles, &c.

Another very frequent cause of cough arises from irritations in and about the rima glottidis. You all know the extreme irritability of that part: it often happens that it becomes slightly inflamed, and then it is in the beginning dry, and shortly afterwards it throws out a thin and acrid secretion, as we shall describe when we arrive at that subject. A violent cough is the consequence, and it is continued until sufficient mucus is torn from the tracheal and bronchial surfaces to moisten the dry state of the membrane, or to soften the acrimonious quality of the irritating secretion. This cough, from its violence, has been called "*tussis ferina*." Whatever, however, be the cause of coughing, the mechanism is the same: it consists in a sudden contraction of all the diameters of the chest, for the purpose of pressing the air through the air-passages with the greatest force, to carry the mucosities with it; accompanied at the same time by a contraction of the glottis, to afford a greater impetus to the air by diminishing the diameter of its column.

The recti-abdominales, arising from the pubes, and inserted into the sternum and cartilages of the fifth, sixth, and seventh ribs, draw the chest directly downwards, and thus act as the antagonists to the sterno-cleido-mastoidei; the two oblique and transversales, having their attachment at the cristæ of the ilia and Poupart's ligaments, pass to the cartilages of the whole of the false ribs, and draw them also towards the pelvis, the quadrati lumborum attached below to the posterior part of the cristæ of the ilium, and to the ilio-lumbar ligaments, are inserted into the last ribs, and, by their contractions, pull those ribs downwards, and fix them, and thus become the antagonists to the scaleni. The

last ribs becoming thus fixed points, the last row of intercostal muscles acting from the twelfth ribs, depresses the eleventh, and fixes them; the tenth are also acted upon and fixed by their intercostals in the same manner; and so on successively to the first; so that you perceive the functions of the intercostals are reversed in the act of expiration, that difference depending upon the position of the fixed points. The triangularis sterni also operate by drawing down the cartilages of the third, fourth, fifth, and sixth ribs. The serrati, postici inferiores, the sacro-lumbales, &c. all depress the ribs.

The result of these actions is to approximate the chest to the pelvis: in doing so, the ribs are also drawn inwards and the sternum downwards, as may be distinctly felt on applying the hands to the chest during coughing: thus, the transverse and antero-posterior diameters are lessened, and, as the diaphragm is elevated at the same moment, the capacity of the thorax is diminished in all its dimensions, the lungs are compressed, and the air driven out with force.

Contraction of the glottis.—At the instant the contraction of the chest takes place, the rima glottidis contracts also, so that the column of air ascending the trachea, acquires additional force to carry the obstructing secretions with it, on passing through the narrow orifice of the opening of the larynx. The peculiar sound of cough is produced, too, by that contraction: such is the care also in spitting: however forcibly you make an expiration, not a particle of saliva will pass the mouth; the lips must be previously contracted, the fluid is then projected, and the sound of spitting is heard at the same moment.

There are several varieties of cough: we shall speak of them when we consider their particular causes.

ADDITIONAL OBSERVATIONS

ON THE

VENEREAL DISEASE;

Being an Extract from the Annual Report of Diseases treated in the Hospital of the 72d Regiment, at the Cape of Good Hope, in 1833.

By THOMAS CLARKE, Esq.

[Communicated by Sir JAMES M'GRIGOR, Bart. with the Author's permission.]

THE observations on the Venereal Disease submitted on a former occasion*, embraced a period of four years; the result of the experience of another year is now to be added.

* Med. Gaz. vol. xiii. p. 860.

Having, during the whole of the former period, had the opportunity and advantage of an interrupted observation of the disease occurring in a body of men constantly under my own eye, and conscious of being free from bias, I was enabled, as I believe, to give a fair and impartial trial to the mercurial and non-mercurial modes of treatment. The result was, as I formerly stated, a confirmation of the fact—a fact which had long before been established by others, that every variety of the primary disease may be cured without the use of mercury; and that this mode of treatment was to be preferred, as accomplishing a cure at a less expense of health, (though not, perhaps, of time, in the first instance);—as incurring a smaller risk of constitutional symptoms;—and as holding out an assurance, that these symptoms, when they do occur, shall be mild and tractable, and easily and effectually removed, with little injury to the constitution.

Were the merits of the question, as to the employment of mercury, to rest upon its necessity alone, I conceive they would lie within very narrow limits; but a far wider range is embraced, and important results implicated. It becomes then a subject worthy of deliberate consideration, not to be rashly taken up, nor lightly abandoned. In this spirit, and with an earnest desire to do justice to truth, as well as to those entrusted to my care, I continue to prosecute the subject.

Having come to the conclusion above stated, I entered upon the last year with a confidence in the efficacy and security of the non-mercurial treatment, which I did not before possess; and the result has been such as by no means to weaken that confidence.

It appears to me that much mischief is done in the treatment of the primary, as well as secondary, disease, by vacillation and impatience; for having, perhaps, been taught to consider and rely upon mercury as a specific, we become impatient of the sluggish process of an ulcer, and are apt to fly to its use without satisfying ourselves of the necessity, or weighing well the consequences. Or we may have some theory in our heads of the necessity of giving this remedy in sufficient quantity to secure the constitution, than which, in my opinion, there cannot be a more erroneous or dangerous principle; for, influenced by

this motive, when constitutional symptoms do appear, we have recourse to a little more mercury and a little more sarsaparilla, until the disease, by its frequent recurrence, and having assailed every vulnerable part of the body in turn, has made such inroads upon the constitution, as to give the patient, at best, but a chance of lingering out a miserable existence. The accuracy of this picture may well be questioned in these latter times, but unhappily it is but too faithful, and by no means uncommon.

What quantity of mercury is necessary or sufficient, or when the constitution may be considered to be secure, would I should think be a matter of some difficulty to determine; but, from what I have seen, the constitution appears to me to be in greatest danger where most mercury is given.

It may be necessary to bear in mind that I am speaking of the disease as it presents itself in a European constitution, under the influence of a climate foreign to that constitution. That this influence is considerable has been already remarked, and in the course of the present observations I shall have occasion to bring under notice one or two remarkable instances, in which its influence is further illustrated.

Before entering upon the occurrences of the present period, it may be well to dispose of the cases which remained at the close of the last. They were two in number, and both of constitutional disease. In the first, the primary disease had been treated with, and in the second without, mercury.

The origin and progress of the former have been detailed, under the head of the fourth case, in the former observations; but before tracing it to its termination, it may be necessary to recapitulate briefly its leading characters.

The primary disease was a deep sloughing ulcer on the glans, which, showing no disposition to heal in what is considered a reasonable time, and there being nothing apparent in the constitution which forbade the use of mercury, this remedy was had recourse to, and the ulcer was healed under its use in nineteen days.

Copper-coloured blotches made their appearance on the lower extremities twenty-four days after his dismissal, for which he was under treatment six weeks. After an interval of seven weeks,

the disease returned in a more aggravated form. The eruption pustular and tubercular, with considerable constitutional disturbance. He was kept under treatment at this time for the space of eight weeks, when every appearance of the disease having vanished, he was discharged. After a lapse of fourteen weeks he returned once more, much altered in appearance, having concealed his condition and held out as long as he possibly could, which he was better enabled to do, having been on detached duty.

The symptoms now were an extensive aphthous ulcer, engaging the whole of the pharynx; constant and very distressing cough; deafness; pains in the larger joints; and an eruption of dark-coloured blotches generally over the body.

Some of these symptoms were apparently removed and others palliated, but nothing could abate the violence of the cough; and it soon became evident that all the organs of respiration were affected. The respiration became more laboured, with a wheezing noise, and the voice stridulous. The chest, when struck, emitted a dead fleshy sound, and no motion of air, or sound of any kind, could be discovered by auscultation. The expectoration, which was at first a glairy mucus, was converted into pus, and occasionally streaked with blood; and the disease assuming many of the characters of phthisis, proceeded rapidly to a fatal termination.

The appearances on dissection were as follow:—In the pharynx there was found the cicatrix of an extensive ulcer: the mucous membrane of the epiglottis was in a state of ulceration, and a deep foul ulcer had formed itself immediately under the rima. The whole of the mucous membrane of the larynx and trachea was highly vascular, and studded with numerous small ulcers. These appearances were continued downwards, and increased towards the bifurcation of the bronchi. The lungs of the right side were one mass of tubercles and vomicae, in various stages, and wholly impervious to air. They adhered every where firmly to the pleura costalis, excepting in a part of the inferior lobe. In this space there were about two pints of turbid serum, mixed with flakes of coagulated lymph, and the surfaces of both portions of the membrane were found coated with this secretion.

The lungs of the left side exhibited the same appearances, adhering also in several places to the pleura, by which several cavities were formed, which were filled with dark-coloured fetid matter.

The internal surface of the small intestine exhibited a dark plum colour, in which there were numerous ulcerations well defined, with elevated and indurated margins. These ulcers became more numerous towards the termination of the ileum, and in the cæcum the mucous membrane was almost totally destroyed. These were all the morbid appearances which were detected.

Upon what particular circumstance, whether of habit, influence of climate, or idiosyncrasy, the fatal result may have depended, or whether they may all have been concerned, must be a matter of difficulty to determine. That mercury was the cause of all this mischief may be deemed an unwarranted assertion: all that is certain is, that it did not prevent it. If it is objected that it was not given in sufficient quantity to guard against secondary symptoms, I would answer, that the system was affected by it, and kept under its influence until the sore was healed. The advocates for moderation would not have sanctioned more. What then have we to guide us in the use of this remedy? since it is admitted on all hands that there are circumstances under which it may act as a poison. There are peculiarities of constitution which may be manifest, but there are also others, and secret influences, against which we cannot guard.

Seeing, then, the possibility of doing harm, and that in no instance coming under my observation, in which mercury has been abstained from, has the disease caused any serious injury to the constitution, much less proceeded to a fatal termination, I feel myself justified in prosecuting that line of treatment; and there is, at least, no discouragement to do so, when I view this case in connexion with the other which was under treatment at the same time, and which resembled it in many respects so closely.

In the latter, the primary sore was situated exactly on the same part, and was as precisely as possible of the same character. It was healed in 38 days, without the use of mercury. Two months afterwards a papular eruption appeared, with slight pains in the elbow-

joints, both of which symptoms were entirely removed in the course of three weeks by the usual treatment. In the meantime, this man, who had at no time been remarkable for sobriety, had fallen into habits of greater intemperance, and these, together with a sudden vicissitude in the weather from extreme heat to cold, as I conceive, brought the disease once more to light. The symptoms on this occasion were an erythematous inflammation of the fauces, pains in the shoulders and elbow-joints, and a pustular eruption from head to foot, but more general upon the lower extremities. At the end of two months he was discharged to all appearance perfectly well, every symptom of the disease having disappeared, excepting a discolouration of the skin on the lower extremities. However, five months afterwards he made his appearance once more with the eruption, now confluent on the lower extremities, but no other symptom of disease, and the general health not at all affected. By confinement to the horizontal posture, simple antiphlogistic treatment, and the local application of a solution of sulphate of zinc, the ulcers were all healed, and the integuments had recovered their natural texture and appearance in the course of two months. Taking counsel of former experience, he has reformed his habits, and fifteen months have elapsed without any return of disease. The cicatrices are still visible, but his health is uniformly good, and his constitution unimpaired.

It will be observed that, in the Return of this year, I have brought every case of venereal sore which has been admitted into hospital, under the head of ulcer of the genitals. This may be considered a very unscientific arrangement, but it has this advantage, that as it pretends to nothing, it cannot mislead. I have already confessed my inability to classify the disease, according to what is called the syphilitic and non-syphilitic character; and the more attentively I observe the various appearances, the more I find the subject beset with difficulties. The distinguishing characters of sores are so frequently blended together as to be almost lost; and if syphilis is to be known with certainty only by the character given to it, of its constant tendency to progress, unless checked by the operation of mercury, all I have to say is, that I have not yet met with syphilis at the Cape of Good Hope.

The cases of ulcers which have been admitted into hospital during the last year, amount to twenty-seven. Although not so numerous as in former years, they have not failed to exhibit the same diversity of character. It would be waste of time to describe the various appearances; suffice it to say, that between the small superficial secreting sore, and the suppurating ulcer with hardened edge and base, there have been examples of every variety which have been observed on former occasions. They have all been cured without the internal use or external application of one grain of mercury. The period under treatment of the simple ulcer has varied from six to fifty days. The average of the whole number rather less than twenty and a half. Of the cases of bubo, which in every instance proceeded to suppuration, the period under treatment averaged thirty-three days.

Every man was discharged fit for duty. Upwards of twelve months have elapsed in some instances, and not less than four in any, and no symptom of constitutional disease has appeared. Shall we then come to the conclusion that not one of these cases has been syphilitic, but the effect of what has been called "morbid animal poisons?" We can hardly do so, unless we admit that the latter are in all respects as noxious to human life as the former, which will leave us with a distinction without a difference. For we have seen on former occasions, sores of precisely the same characters, in the same class of persons, and derived from the same sources, entailing consequences extending to life and limb. How then are we to reconcile these conflicting results? I see no other way of escaping from the difficulty than by supposing, that the poison has of late undergone a change, not a mysterious and inexplicable, but a natural change, the consequence of some alteration in the condition of the infecting subject. The number of prostitutes in this town, with whom soldiers have intercourse, is not great: their haunts are well known, and being aware that apprehension and imprisonment in an hospital (to persons of their habits of life a most grievous punishment) are the certain consequences of disease being traced to them, they have a powerful inducement to endeavour to prevent the communication of disease. This caution on their parts, together with the sweep that is occa-

sionally made of them, are sufficient, I think, to account for the change in the character of the poison, as well as the decrease in its frequency. If then it be admitted that the poison is capable of undergoing a change from malignity to mildness, and *vice versa*, (and of that there is as much proof as can be expected in such cases,) I see no reason to deny to this poison the power of producing a variety of sores of itself, leaving out of question the influence of the receiving habit; but if we at the same time take into consideration the effect of the combined influence, the difficulty to my mind is entirely removed, and consequently I am prepared in all cases of ulcers to admit the identity of venereal poison.

[To be concluded in our next.]

ON THE COMPARATIVE MERITS

OF

DR. BELLINGERI'S AND SIR C. BELL'S WRITINGS

AND OPINIONS ON THE FUNCTIONS OF THE FIFTH AND SEVENTH PAIRS OF CEREBRAL NERVES.

By G. NEGRI, M.D.

On the Physiology of the Seventh Pair of Cerebral Nerves.

IF the comparative view of what has been published at different periods by Dr. Charles Bellingeri, in Italy, and Sir Charles Bell, in England, on the physiology of the fifth pair of cerebral nerves, has excited a certain degree of interest amongst those members of the medical profession who more particularly direct their attention to physiology, I feel confident that what I am going to relate on the physiology of the seventh, will not be found of less importance.

It will, however, appear quite evident to every one, both from what has been already published on the fifth, as well as from what we shall see on the seventh, how highly improper it is for any body to enter into critical arguments against an author's opinions without having first read his works, or, if read, without understanding well the contents of them.

Mr. Alexander Shaw begins his criticism on Bellingeri's opinions on the phy-

siology of the seventh, with the following sentences: "In the second place, the Italian physiologist differs from our English physiologist in regard to the functions of the *portio dura*. The opinion here too, like that in the former instance, is just of such a nature as to present the widest breach between these two physiologists that could be imagined by any one resolved to put them in absolute contrast. Bellingeri conceives that the *portio dura* is a compound nerve; that it is endowed with both motion and sensation. I have shewn that Sir Charles Bell describes it to be a nerve of motion only, and altogether devoid of any property of sensation*."

Sir Charles Bell, when comparing the symmetrical system of nerves with that of the respiratory nerves, in his first paper, read in July 1821, says, "If the nerves be exposed in a living animal, those of this class (the former) exhibit the highest degree of sensibility; while, on the contrary, nerves not of this original class or system are comparatively so little sensible, as to be immediately distinguished; inasmuch, that the quiescence of the animal suggests a doubt whether they be sensible in any degree whatever†." And when speaking of the nerves of respiration, in his paper read in May 1822, he says, "In page 25, we have traced the nervous system in the lower animals, and we have seen that the regular ganglionic system of animals of the lower class is sufficient for motion and sensibility. But that call which gives occasion to inspiration is quite unlike pain from external impression, as the act it excites is unlike voluntary motion. It is an instinctive impulse; powerful in the moment of birth as at any after period, which calls the respiratory muscles into action; and the motion it produces is of that instinctive or automatic kind which is perfect from the beginning."—"A new sense, and a new concatenation of motions, require a new nerve, a distinct centre, or origin, and a new apparatus of muscles‡." And more particularly of the *portio dura*, in the second part of the paper on the nerves of the orbit, he says, "The respiratory nerve of the face performs two offices, one of which is voluntary, as in moving the cheeks and lips in speech; and the other in-

* See Med. Gaz. July 19, p. 562.

† Sir Charles Bell's last work, p. 63.

‡ Ibid, p. 119.

voluntary, as in moving the nostrils in breathing during sleep, or insensibility*.”

Thus it is evident that Sir Charles Bell had not *originally* considered the *portio dura*, together with the other nerves, so called, of respiration, entirely deprived of sensibility. He ascribed to them a power both of involuntary and voluntary motion; and for this *new sense* of action, considered necessary a *new kind of nerve*, distinct from those of common motion and sensation. In what this *new sense* consisted, or by what means the power of involuntary motion was exclusively bestowed on those muscles, which, although under a partial control of the will, also act independently of it, was never stated by the English physiologist.

In relating, however, some experiments on the respiratory nerves, he gives the following statements regarding the respiratory nerves of the face and neck, in his paper read May 2, 1822:—“When apparent death had taken place, the ass was so far reanimated by artificial breathing, that the act of respiration recommenced; these muscles on the face and neck were restored to activity, and become subject to regular and successive contractions, as in excited respiration, whilst the chest remained at rest. These actions continued for a short time, and then ceased; but upon artificial respiration being again produced, the same results followed. This was repeated several times; the animal remaining *insensible during these experiments, and incapable of voluntary motion*†.”

“Upon stimulating the nerves after the death of this animal, it was observed that the class of respiratory nerves retained their power of exciting their respective muscles into action, long after the other nerves had ceased to exert any power; they were evidently of that class which retain their life the longest‡.”

Now, if, according to Sir Charles Bell, “a pure or single nerve has the influence propagated along it in one direction only, and not backwards and forwards§,” how could these involuntary actions of the respiratory nerves of the face and neck have been reanimated by artificial respiration, after the animal had lost all the other powers of motion and sensation, if not by admitting the

combination of these two powers joined together in the nerves of respiration?

The Italian physiologist, when speaking of involuntary muscular action, never ascribes it (as one would be induced to believe, from the incorrect statements of Mr. A. Shaw) to a simple nerve. In mentioning the involuntary actions of different muscles of the face, we have seen them distinctly attributed either to the intermixture of the muscular branches of the fifth with others of its ganglionic portion, or to anastomosis of the latter with filaments from the seventh. In endeavouring to explain the involuntary actions of the muscles of the internal organ of hearing, he refers them to the junction of the ganglionic portion of the fifth with other filaments from the seventh, when the involuntary motions of the iris are explained by the combination of two distinct nervous powers, from the third pair, and the ophthalmic branch of the fifth, which constituting a *new organic centre of action, partially independent of the will* (the ophthalmic ganglion), becomes thus the moderator of that delicate dioptric apparatus. Moreover, if any voluntary motion may be ascribed, or has been observed in the iris, this has been distinctly referred to the mere influence of the third, and not of the fifth.

Still Mr. A. Shaw, when speaking of the supposed coincidence of opinions of Sir Charles Bell and Bellingeri, says,—“The English physiologist maintains that a nerve consisting of a single root can possess only one of the two functions, sensation or motion; that it cannot have these incongruous properties combined. Does Bellingeri subscribe to this fundamental principle of the whole discoveries? In each of the two nerves, which are the subject of his dissertation, he contradicts this principle in the most decided manner. The large root of the fifth he represents as *confering both motion and sensation*; and he affirms the same thing with regard to the *portio dura*! The only thing in common established between these two authors is simply this: they both composed papers in which the names *portio dura* and *fifth pair* occur! Fluelen, with ‘his figures and comparisons,’ could have devised a far better parallel*.”

* Ibid. p. 210.

† Ibid. p. 141.

‡ Ibid. p. 142.

§ Ibid. p. 232.

* Med. Gaz. July 19, p. 563.

Having already shewn how far Mr. A. Shaw's statements are *correct* in regard to the ganglionic portion of the fifth, let us proceed with our parallel between these two authors' opinions on the seventh.

Sir Charles Bell, in his first paper, read in July 1821, says: "The respiratory nerve of the face, being that which is called *portio dura* of the seventh.....goes off from the lateral part of the *medulla oblongata*, and escaping through the temporal bone, spreads wide to the face. All those motions of the nostrils, lips, or face generally, which accord with the motions of the chest in respiration, depend solely on this nerve. By the division of this nerve, the face is deprived of its consent with the lungs, and all expression of emotion*."

"The respiratory nerve of the face arises from the superior and lateral part of the *medulla oblongata*, close to the *crus cerebri*, and exactly where the *crus cerebelli* joins the *medulla oblongata*. The other respiratory nerves... arise in a line with the roots of this nerve†."

"The nerves on which the associated actions of voluntary and excited respiration depend, arise very nearly together. Their origins are not in a bundle, or fasciculus, but in a line or series, and from a distinct column of the spinal marrow. Behind the *corpus olivare*, and anterior to that process which descends from the *cerebellum*, called sometimes the *corpus restiforme*, a convex strip of medullary matter may be observed; and this convexity, or *fasciculus*, or *virga*, may be traced down the spinal marrow, between the *sulci*, which gives its rise to the anterior and posterior roots of the spinal nerves. From this tract of medullary matter, on the side of the *medulla oblongata*, arise in succession, from above downwards, the *portio dura* of the seventh nerve, the *glosso-pharyngeus* nerve, the nerve of the *par vagum*, the *nervus ad par vagum accessorius*, and, as I imagine, the phrenic, and the external respiratory nerves‡."

The characteristic distinctions of these nerves, according to Sir Charles Bell, are the following:—"They do not arise

by double roots; they have no ganglions on their origins; they come off from the *medulla oblongata* and the upper part of the spinal marrow*."

Bellingeri, in his anatomical dissertation, cap. ii. *De septimo nervorum pari, sive de nervo faciali*, describes its origin as follows:—

§ LVI. p. 100.—"This nerve, as I had an opportunity of observing, together with the celebrated professor of anatomy Rolando, and the doctor of surgery Gallo, dissector of anatomy, takes its origin, in the first instance, from the medullary fasciae of Malacarne. We saw, in fact, a medullary bundle on either side, about the size of the fourth nerve, proceeding from the exterior of the medullary fascia, and from about the middle of its length. This bundle, forming a concave arch upwards, ran round the inferior extremity of the corpus olivare, appearing to us to have some connexion with the latter: it then, continuing nearly of the same thickness, ascended to the outer side of the corpus olivare, and a little apart from it, but over the corpus restiforme, and having a manifest connexion with it. About the middle of the corpus restiforme, the fasciculus seemed to us to be joined by a medullary filament given off from the fourth ventricle; and then, upon reaching the base of the corpus restiforme, it fell in with the trunk of the eighth pair, or acoustic nerve, in company with which, proceeding through the quadrilateral fovea of Malacarne, leaving, behind the annular prominence, the substance of the brain, it became enveloped with the pia mater, and thus formed a nervous trunk. We all distinctly saw, admired, and were greatly delighted with this structure; our subject being an adult man, whose brain was of a good consistence. The same structure, however, is not invariably found in all subjects; oftentimes it is not a bundle, but expanded filaments, which are observed at its origin: sometimes, too, they come out not beneath, but above the corpus olivare.

"This origin of the facial nerve, as observed by us, perfectly coincides with that described by Girardi and Santorini; who say that the *portio dura* emerges above the arciform process†, and some-

* Last work, p. 65.

† Id. p. 70.

‡ See paper read in May 1822, "Origins of the respiratory nerves," p. 129.

* Last work, p. 64.

† The arciform process is the name given, by Santorini, to those oblique fibres which surround the lower extremity of the corpora olivaria.

what above the corpora olivaria, from the inner and lower part of the annular prominence, where it is connected with the peduncles of the brain; so that this portio dura entirely corresponds with the crura cerebelli."

§ LVII. pp. 103-105.—"Further, the facial nerve consists of two portions—one, the larger, which is lateral; the other, which is internal, smaller, first discovered and accurately described by Wrisberg. The larger portion, at its commencement, resembles a little band, which farther on becomes fibrous, and, on leaving the substance of the brain, is enveloped with the pia mater, and appears as a slender tapering nerve. But the lesser portion consists of two or three filaments, with very delicate roots, which proceed partly from the substance of the pons in the quadrilateral fovea of Malacarne, intermediate between the facial and acoustic nerves, and partly emerge from a spot close by the origin of the glossopharyngeal nerve. We have borrowed the description of this portion from Scarpa, who represents the origins of the two parts of the facial in a neatly and beautifully-executed engraving*.

"Soemmering says that some of those filaments arise from the annular protuberance itself; and Vieussens, in speaking of the facial nerve generally, states, 'that they adhere on both sides to the annular process, which gives off to them (namely, the portio dura and mollis) some minute fibres.' But the lesser portion of the facial is situated between the larger portion and the acoustic nerve, and its fibres, as they proceed onward, unite into one or two nerves. The minor portion at length approaches the greater, and forms a close junction with it: sometimes, however, this is not the case, unless in the internal auditory canal, and then it seems, in the cranium, to constitute a part of the acoustic nerve. On entering the internal auditory canal, it recedes from the acoustic, becomes intimately connected with the facial, emerges along with it from the cranium through the aqueduct of Fallopius, and is distributed to the face.

"Cuvier also mentions this double origin of the facial nerve; one portion of which, he says, has a laminous form, the other a fibrous aspect. This double ori-

gin is more remarkable in the calf, for as the common root proceeds, another is added to it, arising from a considerable ganglion situated in the posterior part of the nervus vagus, and which communicates with the great sympathetic. Its origin from the ganglion consists of two or three filaments, which, as they unite, become much enlarged*. I myself, in company with Dr. Riberi, saw a thick and tapering filament in the dead body of a woman, proceeding from the middle lateral and somewhat superior part of the corpus olivare, and uniting with the facial nerve, which we observed to be distinctly divided into two fasciculi.

"Thus the origin of the facial nerve should be threefold—namely, as it proceeds from the medullary fasciæ, from the restiform bodies, and from the corpora olivaria: perhaps we should also add, from the pons varolii."

I shall proceed, in my next article, with the physiology of the seventh nerve.

Oct. 6, 1834.

SURGICAL CASES

Treated in the Naval Hospital of St. Petersburg.

By HARRY LEEKE GIBBES, M.D.

Member of the Royal College of Surgeons of London.

CASE I.—*Violent Contusion of the Hypogastrium — Antiphlogistics — Recovery.*

TICHAN DENISOFF, æt. 47, a helper in the Admiralty stables, of robust make and sanguine constitution, was received into the General Naval Hospital of St. Petersburg, with a severe contusion of the lower part of the abdomen, from the kick of a horse, late in the evening of the 26th June, 1833. Syncope continued for some minutes after the injury, but on admission to the hospital re-action had fully taken place.

Six grains of Calomel, with ʒss. of Jalap, were administered, and ʒxxx. of blood taken from the arm.

27th.—Early this morning, as the bowels remained constipated, ol. ricini, ʒjss. was given, and a stimulating enema thrown up; and as no urine had been passed, I applied the catheter, and drew off two pints tinged with blood. In the evening, tension and

* Disquisit. Anatom. de Audit. et Olfact. p. 52, Tab. viii. fig. 5.

† Leçons d'Anat. Comp. tom. ii. p. 146.

* Cuvier, op. cit. t. ii. p. 227.

tumor of the abdomen, from the umbilicus to the pubis, and extending to the lumbar regions, had taken place. Fifty leeches were applied over various parts of the swelling, and the bleeding encouraged. The bowels still continuing inactive, I gave him one drop of croton oil, with directions that another drop should be repeated at the expiration of three hours, if required.

28th.—Has taken two drops of the ol. croton with good effect; ten or twelve copious black and fetid stools having been voided. Warm fomentations of chamomile, poppy heads, and cicuta, constantly applied around the belly, evaporation being prevented by surrounding the whole with prepared oiled-cloth.

29th.—The patient much excited. Pulse 115, and full; pain on pressure increased.

V. S. ad lb. ij. instant.

8 P.M.—Blood bled and cupped. Feels relieved. Pulse reduced to 95, and soft. Parts less tumid and painful.

A dose of the saline Senna mixture to be occasionally taken.

30th.—Has had some refreshing sleep towards morning. Catheter applied three times daily. Bowels twice evacuated; pulse 90; swelling subsiding. Visited him at 9 o'clock in the evening, and, as he complained of a dull obtuse pain in the region of the kidneys, ordered two cupping-glasses to be applied over each loin, by which a sufficient quantity of blood was abstracted.

July 1st.—Inability of making water still demands the use of the catheter. Urine highly coloured, and rather fetid, depositing a lateritious sediment. Mucilaginous diluent drinks continued, with now and then a dose of the laxative mixture. In the evening a warm-bath. It is probable that the dark colour of the stools and urine was occasioned by the blood thrown out by the capillary vessels of the intestines and urinary passages, in consequence of the violence of the concussion—a sort of contrecoup.

2d.—Has enjoyed some hours' sleep. Urine clearer, and the tumor considerably diminished. Pulse 85, and soft. The warm fomentations persevered in, as affording much relief.

3d.—Found the patient labouring under occasional disposition to vomit, with oppression at the præcordia, which I

suspect has been induced by cold drinks, imprudently given to him.

Prescribed an effervescent draught, with ten drops of the *Liquor. Anod. Hoffmanni*, every two hours, and the constant application of a stone bottle of hot water across the region of the stomach.

In the course of a few hours he was relieved, and confessed having drunk a tumbler of cold quass (a sourish beverage, prepared from rye-flour and ground malt), and that he had repeatedly been affected in a similar way, after inebriety or irregularity of diet, ever since a severe attack of the *atmospheric cholera*, or epidemic of the summer of 1831.

From this time to the evening of the 7th, I was unable, from indisposition, to attend him; and it was with regret I learnt that he had had a relapse on the night of the 3d, accompanied by singultus, which now was incessant, producing insomnia and extreme anxiety. Various antispasmodics,—as musk, castor, camphor dissolved in aether, tinct. opii, &c.—had been ineffectually tried. Having observed the good effect of a blister to the epigastrium, in assuaging obstinate hiccup, in a case of severe symptomatic fever after lithotomy, I ordered an oval one, of six inches in length by four in breadth, to be immediately applied, and the effervescent draught, with a small quantity of Hoffmann's drops, to be renewed every two hours.

8th.—On visiting him this morning, I was delighted to find that the hiccup had gradually ceased, after the blister had lain on four hours, and was beginning to rise, and that he afterwards obtained some sleep. The urine, too—whether from a stimulus given to the bladder by the absorption of cantharides,—began towards the afternoon to flow in small quantities.

Allowed some warm port-wine negus twice a day.

9th.—The patient considerably reduced by the long-continued state of irritation. Prescribed a light tonic mixture of *Infus. gentianæ c. Tr. card. comp.*

10th.—Better. The catheter only passed late every evening, in order completely to evacuate the bladder, and afford him a better chance of sleep; gentle stimulating frictions to the abdomen night and morning; the central part of the blister to be kept open.

11th.—The bowels beginning to resume their functions naturally, and the urine continues to flow. A broad flannel bandage ordered to be constantly worn from the hypogastric regions to the hips, as well for the sake of warmth as to support the parietes of the abdomen. A light nourishing diet allowed.

14th.—The catheter omitted. From this date his convalescence was rapid.

August 1st.—Blister healed, and diet increased.

6th.—Feels well in all respects, and wishes to leave the hospital.

11th.—Dismissed, cured, and strictly enjoined to continue to wear the flannel bandage, and abstain from irregular habits.

CASE II.—Compound Fracture of the Leg — Attack of Scurvy — Saline treatment — Recovery.

Michael Timopheef, æt. 39, was placed under my care, at the General Naval Hospital of St. Petersburg, on the 19th of June, 1828, with a compound fracture of the left leg, four inches above the ankle-joint, the consequence of a fall from a vessel building in the Great Admiralty Yard. The tibia was fractured obliquely, and projected half an inch. Reduction was speedily effected, and nothing worthy of remark occurred, but that the treatment proved tedious, owing to the irritable habit and restlessness of the patient. I have been accustomed, with a few exceptions, to employ the straight position, with junks, as formerly, at St. George's Hospital.

By the 15th October he was enabled to use crutches, the limb being supported by a roller and pasteboard splints.

On the 29th November he was dismissed, cured.

From this period I heard nothing of him till the 2d of April, 1833, when he was readmitted for considerable lameness of the left leg, and scurvy, produced by defective nourishment during the long fast of six weeks preceding Easter, and exposure to wet and cold during the thaw. The characteristic symptoms were—lividness and flaccidity of the countenance; ecchymoses; rigidity and contraction of the back of the legs and hams; extravasation under the tunica adnate, and in the cellular membrane beneath the palpebræ; the teeth nearly hidden by spongy and bleeding gums, with the most offensive breath; and so great was the dyscrasia sangui-

nis, that the body was covered with scorbutic petechiæ; skin rough and arid; urine scanty and high coloured; bowels usually costive—when evacuated, stools black and foetid; pulse slow and feeble; moral depression very great. In this state of living decomposition, if the expression may be allowed, great is the number that, during the space of twenty-six years, have come under my observation. On examining the leg, I found that the old cicatrix had ulcerated in three or four places, and that the ends of the bones formerly fractured were slightly moveable on each other, but no crepitation was perceptible. After the usual ablution of a warm-bath, he was put on a light nourishing diet: beef soup at dinner and supper, with fresh vegetables, especially sorrel, of which vast quantities are cultivated in this neighbourhood; water cresses, green onions, horse-radish, cranberries, and lemons, were also liberally supplied. The whole body was ordered to be washed night and morning with tepid camphorated vinegar and warm fomentations of a strong decoction of aromatic herbs, acetum camphoratum, and a little acid. muriat. dilut. to be constantly applied to the hams, back of legs, and over the wound. The following antiscorbutic mixture was prescribed.

R. Extract. Turionum Pini Sylv.; Extract. Amari, aa ʒj.—solve in Infus. Calami. Aromat. ʒvj.; Succ. Baccar. Oxycocci, Spiritus Frumenti, aa ʒiij.; M. Sumat æger. ʒij. 4ta quaq horâ.

As an antiseptic gargle,

Decoct. Cinch. Peruv.; Mel. Rosarum; Acid. Muriat. dilut. and Tinct. Myrrhæ.

April 16th.—Health and spirits improved. The cicatrix has completely given way superficially, and the callus so loosened as, to present to the feel what is termed an artificial joint; the use of junks and a foot-board being required to support and steady the foot.

May 6th.—Increase of diet allowed, with stronger lemonade, to which port wine is added. Absorption of the ecchymosed fluids proceeding rapidly; gums subsiding; breath far less offensive.

Detergent gargle to be continued.

24th.—Reunion of the bones commencing; wound in a healing state; bowels regular.

30th.—Much better. A quart of the hospital beer, containing the tips of the fir-pine and horse-radish infused, allowed daily, with half a pound of roast beef extra at dinner; and, to his great delight, I permitted him to eat sour-kraut. It may not be here out of place to observe, that the allowance of salt to each patient on full diet is at the rate of $\frac{3}{4}$ j. per diem, half of which is employed in the kitchen for seasoning their soup; a quantity well adapted to the taste of the Russian, who from his infancy is accustomed to every thing sour and salt, as cabbage, cucumbers, beet-root, and various kinds of mushrooms, salted for winter use. Salt-fish and herrings, and the little beef they consume during the greater part of the year, is usually salted. Their black rye-bread, of a sourish quality, is eaten sprinkled with salt, and the whole is washed down with quass. As a due admixture of animal and vegetable food (in northern climates at least) may be said to be the best preventative of scurvy, so here the too frequent want of it, with the numerous fasts; the immoderate use of votky, or distilled rye spirit; and the sedative effects of the long winters, strongly dispose to it; and, were it not for the salt and antiscorbutic nature of the diet of the lower classes, scurvy would no doubt be far more prevalent.

When Dr. Stevens was in St. Petersburg the summer of last year, he visited the naval hospital, accompanied by the medical officers, and the patient in question was pointed out to him. I have now quitted the Russian service, in the hope of shortly returning to my native country, or I would not fail to give a fair trial to the saline treatment in scurvy, so strongly recommended to me by the doctor.

July 15th.—Continues to improve. Allowed full diet, with two quarts of beer daily. Reunion of the bones firmer.

August 10th.—Wound nearly healed.

15th.—Began to use crutches; paste-board splints over the roller.

September 7th.—Wound well cicatrized. The limb, though nearly an inch shorter than the other, owing to the state of the ham and flexor muscles, and to the disturbance consequent on the frequent fomentations of these parts, was sufficiently strong to enable him to hobble about, with the assistance of a high-heeled shoe. It may not be im-

probable that an excitement to ossification was partly induced by the friction of the bones on each other, though to the wonderful agency of the vis medicatrix naturæ in restoring energy to the system, the favourable result must be ascribed.

October 29th.—Dismissed cured, but unfitted for duty.

In the voyages of the early circum-navigators we read of the breaking open of the cicatrix of old wounds during the baneful prevalence of scurvy on board their ships. In the hospitals of St. Petersburg and Cronstadt the same effects are of constant occurrence; but I am not aware that a case of disunion, and subsequent reunion, similar to the present, has yet been recorded.

On the 9th of December the subject of this case left the service, with the usual allowance; and, as I formed one of the committee appointed for the survey of those to be discharged or invalided, it gave me great pleasure to meet and prove useful to my friend Iwan Nikitin, on whom I operated for sub-clavian aneurism in January 1823, and whose case was published in the *Medico-Chirurgical Transactions* of that year. His arm remained perfectly restored, and he now presented himself for his discharge and pension, having completed the term required.

St. Petersburg,
Sept. 7, 1834.

AQUEOUS DISCHARGE AFTER PARTURITION;

WITH THE MORBID APPEARANCES.

To the Editor of the Medical Gazette.

SIR,

THE communication of Dr. Ashwell on "Aqueous Discharge after Parturition," in your number for September 6th, has interested me much; and the profession in general cannot but feel under obligation to him, as I do individually, for his valuable remarks and cases, and for having drawn attention to the subject. Having myself met with an instance of the kind some months ago, which then made a strong impression upon my mind (from the novel phenomenon of a *very* profuse watery discharge from the uterus),

I have perused Dr. A.'s paper with peculiar satisfaction and pleasure, and am induced to think a report of the case may at this time be acceptable to your readers.

As my patient unfortunately died, an opportunity was afforded me of performing a *post mortem* examination, whereby the history is rendered more complete than either of those furnished by Dr. Ashwell, and whence, perhaps, some idea of the nature of this singular affection may be formed.

CASE.—In the month of March, 1833, I attended Mrs. —, æt. 29, the wife of a respectable tradesman in this town, in labour with her fourth child. She had from her youth lived in the enjoyment of what might, in her, be well termed rude health, having, however, a goitre since the period of childhood, which had now attained a large size, and had increased in magnitude with each gestation, though a certain diminution took place after delivery; but within the last few months she had experienced a considerable impairment of her general health, to which her looks testified. She had become highly “nervous,” lost a good deal of flesh, and the wonted colour had forsaken her cheeks; yet her chief complaint was of pain, and a sensation of heat in the situation of the left ovary, attended with tenderness under pressure.

The birth of the child was quite natural and expeditious, although there was a slight retention of the placenta, owing to a minute adhesion to the left side of the uterus, which required to be broken through by the introduction of the hand into this cavity. The operation was borne remarkably well, and at the termination of the first twenty-four hours she was as comfortable as any woman could be.

When beginning to act upon the bowels, I found that they had been grievously neglected during pregnancy. The doses of purgative medicine necessary were therefore unusually great, and the quantities of scybala, and dark and diseased faeces, brought away by them were inordinately large. This foul state of the bowels, as might be expected, gave rise to a severe form of intestinal irritation, accompanied by a rapid pulse of 120, violent palpitation of the heart, pain of head, &c. In short, the symptoms of this disorder, so well

delineated by Dr. Marshall Hall, were here conspicuous. The lochia were natural for the first three days, after which no discharge appeared; and at no period could milk be procured in the breasts despite of all our best exertions.

Under the steady and long-continued use of purgatives, the above state of the alvine functions was at length rectified, her strength at the same time demanding the support of mild and bland nourishment, and some of the less powerful diffusible stimuli. In the space of a month her recovery might be pronounced good, though the pain continued in the left iliac region, together with a frequent pulse and unmitigated palpitation.

In April, 1834, my services, as her accoucheur, were again commanded, and in every respect the labour was natural and easy, excepting that there was a greater discharge of coagulated blood than usual, both attendant on and after the expulsion of the placenta.

Her symptoms had been incessantly and carefully watched by me from the earlier months of pregnancy, and even before she was pregnant; during the whole of which time she had suffered severely from the pain in the left side of the abdomen, as well as from palpitation of the heart, and the pulse was scarcely ever under 120. In the early months there was a strong disposition in the bowels to become again loaded, as during her former period of breeding, and constipation for only one day was invariably productive of aggravated sufferings: consequently, when under my advice, she took repeated doses of castor-oil and laxative electuary as often as they were required.

About the sixth month she went a few miles into the country, to the house of a relation; and whilst there, was bled by a respectable practitioner of a neighbouring town for the relief of the pain in the left iliac fossa. Some alleviation followed the loss of blood for a few days, and she was advised to lose more if the pain recurred. Nearly a month afterwards, at her own request, I abstracted a few ounces of blood from her arm, as the pain was then as severe as ever. On account of the pallid aspect of the countenance and prolapsus, I was adverse to depleting at all; and the escape of the above small quantity admonished me not to proceed. She

fancied herself, however, somewhat easier after this scanty venesection.

A tendency to swelling had for some weeks been perceptible in the lower extremities, and in the face also there were manifest some signs of general effusion; in fact, the *aspect* of the patient was *anasarcous*. And in this critical situation strong fears were naturally excited in my mind as to her recovery after parturition.

The first four days subsequent to her delivery passed over tolerably well, and on the fifth some milk was secreted in the mammae. Up to this day the lochial discharge had been flowing constantly, though sparingly; but now it ceased, and there occurred the very remarkable phenomenon of successive copious discharges of a clear watery fluid from the uterine cavity, at intervals of about twelve hours. The quantity passed at each time was estimated at two pints, and its accumulation within the uterus occasioned much uneasiness, from distention previous to its expulsion, which was generally unattended with pain. It was perfectly inodorous, and the napkins were no more stained than if they had been immersed in fresh spring water. For the space of six days this singular evacuation lasted, and at the expiration of this time, when it terminated rather abruptly, my patient had both rapidly and greatly lost ground, and was further irremediably declining in strength. The milk remained in the breasts only one day. A fatal exhaustion was too plainly approaching; the pain in the left ilium and the unnatural action of the heart persisted, though with less violence, proportionate to the diminished powers of life. Delirium came on three days before her death, which concluded the scene on the seventeenth day after her confinement.

Section cadaveris.—All the viscera of the thorax and abdomen were healthy except the uterus and left ovary. The internal surface of the uterus presented three elevated masses, having both a *fungoid* and *melanotic* appearance, more resembling what has been designated the “cauliflower excrecence” than any other morbid or disorganized production to which I could compare them. The largest of these elevations was about equal in size to a penny piece; the two others were probably half as large. Their surface was covered with a thin

layer of dark half-coagulated blood; the adventitious substances were intimately adherent to the lining membrane, so that they were immovable by the finger or handle of the scalpel.

In the left ovarium there was nearly half an ounce of pure pus, and the organ itself was surrounded by some adhesions formed by coagulable lymph.

It was unfortunately out of my power to bring away the morbid parts, which would have admitted of being fully shewn in a drawing.

The remarks I have to offer on the foregoing case are very few, as I look upon those of Dr. Ashwell peculiarly pertinent, and explanatory of the general nature of the subject. It were needless to relate the various means employed in the medical treatment, since the detail would be foreign to the object of my present letter. Suffice it to say, that no remedy was omitted that held out the hope of relieving such formidable symptoms, and that nought but a short palliation of them was procured.

Like Dr. Ashwell, I had looked in vain for an account of this singular malady in the best obstetric authors within my reach; and yet I cannot but imagine that it has fallen under the observation of other practitioners. Now that it has been brought before the notice of the profession, it is very probable that instances of the kind will be remembered by others, and that in future it will be readily recognized.

From the actual state of parts found after death, I cannot agree with Dr. A. in regarding the aqueous discharge as the product of *disordered function*, merely in the mucous membrane of the uterus. Whatever might have been the cause of it in the cases he has just favoured us with, I have no doubt in my own mind but that, in the case which forms the subject of this communication, it proceeded from those foreign growths discovered attached to that structure, as it is well known very profuse limpid secretions are very general concomitants of such analogous excrecences.—I beg to subscribe myself, sir,

Your very obedient servant,
G. BURY.

Farnham, Sept. 27, 1834.

ON THE
CURE OF POLYPI IN THE MEATUS
AUDITORIUS EXTERNUS,

With Sulphate of Zinc.

To the Editor of the Medical Gazette.

SIR,

I OBSERVED in your number of Saturday last a letter from my friend and colleague, Mr. A. C. Hutchison, on the successful employment of a strong solution of sulphate of zinc in the treatment of nasal polypi; and beg leave to add, that since he kindly informed me of Mr. J. Dallaway's using it, I have had at least six cases in which it has been the means of cure. In the first three or four cases it was the sole treatment. I believe one of them, in a youth of 14, to have been an example of the severer form of the complaint, the polypi completely filling the anterior nares, and apparently extending to the antrum, and toward the forehead. At first I directed a solution (℥j. ad f. ℥j.) to be injected upon the polypi, until it occasionally entered the throat. As soon as he could in any degree sniff the liquid, I prescribed, as in all my cases, that he should do so, lowering the solution to ʒss. ad f. ℥j., and cautioning him, that if he swallowed much of it he would be very sick. To the best of my recollection the boy got well in about three months. In those examples which have more recently presented themselves to my treatment, I have not scrupled to use the polypus forceps in the first instance, where they might readily be applied with advantage to any portion of the diseased structure. This I have done merely to save time, and not from any diminished confidence in the efficacy of Mr. Joseph Dallaway's remedy. I have never found any evil result from its being sniffed up the nose.

The polypi which are commonly found in the nares are spheroidal hollow bags attached to the Schneiderian membrane, or to each other, by comparatively narrow necks. I have certainly seen them contract and relax again, more than once (I think I may safely say three times), after their removal to a basin of water. But I am jealous of attributing to them, on that ground, an independent life. We have much fuller evidence that *hydatids* are distinct animals, and yet the mind hesitates to allow it.

I never saw a polypus in the meatus auditorius externus analogous to those of the nose. The former, from all my experience, are not hollow. Although they are spheroidal, and *shrink* when torn from their attachments, they do not exhibit the slightest appearance of active movement. They generally spring from a very small orifice in the cutis, or it may be in the cartilage of the tube, and consist of a very loose spongy texture, full of blood and serum, and invested with the same delicate covering which all granulating sores exhibit. I believe them to be nothing else but "*proud flesh*." The granulation is, indeed, unusually exuberant, so as to form a very narrow-necked fungus; but we have all seen fungi on other parts precisely analogous, and which may be described as the same thing with a polypus of the meatus, excepting only in their magnitude and situation. A minute portion being extirpated from the middle of the toe-nail in scraping or paring it, leaves a wound surrounded with pressure, which, if neglected, will shoot up exactly such a fungus as in the ear would be called a polypus. However, the strong solution of sulphate of zinc is equally beneficial for what is called polypus in the ear, as for that in the nose. I have tried it in abundance of instances, and have generally found ℥j. ad f. ℥j. sufficient. I need not trouble you at present with more than a simple statement of the fact, but should rather apologize for this intrusion on your columns, as I hope shortly to detail some of the cases in a work with which I have been many years engaged, upon Diseases of the Ear, and which, if my other engagements allow, will appear shortly.—I am, sir,

Your obedient servant,

THOS. CHEVALIER,

Consulting Surgeon to the Westminster
General Dispensary.

62, Torrington-Square,
Oct 6, 1834.

CHRONIC RHEUMATISM

SUCCESSFULLY TREATED BY TARTAR
EMETIC.

To the Editor of the Medical Gazette.

SIR,

IN submitting to the notice of the profession the following case of chronic

rheumatism, successfully treated by tartar emetic ointment, there is, I am aware, little new in principle; but the length of time which it had baffled every system of treatment may render it not altogether devoid of interest.

In the spring of 1828 I was applied to by a gentleman of high military rank, labouring under rheumatism, which he said first attacked him during his campaign in the Peninsula, but which, for the last ten years, became so distressing as to deprive him of the use of one or other extremity for the greater part of every year.

I collected from him the following facts:—

In 1818 he retired to the country, being much attached to field sports. The attacks became so severe during the ensuing winter, that he was confined to his bed for two months. Each succeeding winter was attended by one of those tedious fits, which never left him until the spring was far advanced. Being now no longer able to enjoy his favourite amusements, he broke up his establishment, and came to reside near London for additional advice. I saw him there in company with his medical attendant, a general practitioner of some eminence. From him I learned that there was nothing that science or experience could suggest that had not already been employed. Under this impression I proposed a consultation, at which some of the ordinary medicines were prescribed, but with no better success. To this succeeded another and another, with similar results.

In the summer of 1830 his general health became so bad, that it was deemed advisable to suspend all medicines; and with this view he was sent to Buxton to try the effect of the waters. He drank them under advice, but found no relief. He returned home early in October, resolved to submit to patience and flannel. His general health was much improved, though the arm and hip, the parts generally affected, were still very painful. The employment of colchicum and other internal remedies had disturbed his digestion so much, previous to his leaving for Buxton, that nothing could induce him to resort again to internal remedies. For three months he pursued a system of negative medication, waiting patiently for the results of the Buxton waters. The tartar emetic ointment was now ap-

plied for the first time. Why it should have been neglected so long, I cannot account for: its effects were very surprising. The moment the pustules appeared, the pain began to subside, which, as they matured, completely left him. Two or three successive crops of pustules were kept up, in consequence of the pains occasionally returning; but at the expiration of about a month from the first application of the ointment, and four from his visit to Buxton, he was free from all pain—a feeling which he had hardly enjoyed since 1818. His strength and general health rapidly increased, and in the ensuing year (1831) he found himself so perfectly restored that he again broke up his establishment near town, and retired to the country to pursue his favourite sports, of which he was passionately fond. Since that time, he has had many incipient attacks, which he invariably removes by the application of tartar emetic ointment. What is singular, is, that for the last three years he has not been confined, by rheumatism, to his house for twenty-four hours, though, for the ten previous years, he was, upon an average, confined five months every year. Some questions of pathological importance present themselves here, but pending the experimental inquiries of the two eminent French professors, Chomel and Bouillaud, upon the nature and seat of this disease, I shall confine myself to facts, without dwelling more particularly on the mode of treatment; which was such as is generally advised in such cases. Many, doubtless, will object to facts of this nature, as inclining too much to the humoral doctrine; to such I can only say, that there are few whose practice is not influenced by that doctrine, unless they are reduced to the happy condition of the man in Moliere, who was speaking prose for forty years of his life without knowing it.

I am, sir,

Your obedient servant,

RICHARD BURKE, M.D.

4, Bolton-Row, Oct. 1, 1834.

P. S.—The general details of this case, with a few others, shall appear in another form.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

SOMNAMBULISM. *The extraordinary Case of Jane C. Rider, the Springfield Somnambulist; being the substance of a Lecture delivered before the Springfield Lyceum.* By L. W. BELDEN, M.D.

A FEW months ago we gave a short notice of this girl's case, picked up from the American journals: the publication of Dr. Belden's lecture—re-published here in a cheap form—renders it unnecessary to glean or compile further on the subject. Those who are curious about the phenomena of mind, as influenced by bodily infirmity, will be glad to peruse this little work. It details some very remarkable examples of the acuteness of over-excited organs, particularly with how minute a portion of light the retina can perform its functions. The term *somnambulism* but ill expresses the collection of facts detailed in the lecture, *walking in her sleep* being, in truth, only the prelude to Miss Rider's extraordinary performances.

Nouveaux Elémens de Chimie theorique et pratique, à l'usage des Etablissements de l'Université. Par R. T. GUERIN-DE-VARRY, Docteur es Sciences, &c. Bruxelles.

THIS is the neatest abstract of elementary chemistry we have yet seen. The author, a disciple of M. Chevreul, of Paris, to whom he dedicates the work, teaches clearly and concisely a number of useful things, which we should in vain seek in performances of more cost and pretension. From Dumas and Berzelius he has selected much important matter, which he presents to us in a popular form. His preliminary notions on physics, as connected with chemistry, are well drawn up; and we particularly admire the brevity and perspicuousness with which he states the doctrines of equivalents and atoms, giving the modern notation of the latter, as invented by Berzelius, and followed by most of the foreign authorities. The distinction of the simple bodies into metalloids and metals is also here adopted;

and we can strongly recommend to the student many of the practical hints which he will find scattered through these volumes.

OSSA HUMANA: *consisting of numerous highly-finished Lithographic Drawings, on fine imperial folio paper, with copious References in Letter-press.* By R. B. CUMMING, Pupil of St. George's Hospital.

THE title of this performance is so amply set forth by the author, that it leaves nothing for us to describe. We may say, however, that it is correctly as well as copiously announced. The lithographic impressions are all that can be desired. The bones are represented in whole and in part, of the natural size, accurately drawn from nature. The press, we are glad to see, teems with illustrative works just now for the use of the anatomical student, among which we certainly know of none possessed of more merit than Quain's plates of the muscles, and Cumming's drawings of the bones; the latter, however, are complete,—the last of the four fasciculi of which the *Ossa Humana* consisted being recently published.

MEDICAL GAZETTE.

Saturday, Oct. 11, 1834.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

PORTUGUESE MEDICINE.

A ROYAL POST-MORTEM.

WERE we to take the account of the morbid appearances found in Don Pedro's body as a specimen of the state of medical science in Portugal, we should perhaps be thought to imitate Cobbett pulling a King's speech to pieces, and pretending to seek in it “a well of English undefiled.” But although we can make every allowance for documents of this sort, drawn up with court formality, ill adapted to display the qualities which a hyper-

criticism might demand; yet are we obliged to confess that this Portuguese "autopsy," by authority, is really a very poor affair.

Cutting off the head and tail pieces, which constitute the principal bulk of the report,—though containing merely the titles of the deceased and of his *post-mortem* examiners, the whole of the matter is comprised in the following:—

"ABDOMINAL CAVITY. — No fluid. Omentum and peritoneum *rather too pale*, appearing to be *thickened by effusion of bile*.

"Gastric mucous [membrane?], the colour changed in the posterior part towards the spleen.

"Hypertrophy of the great lobe of the liver, and the same altered in colour, being too dark.

"Spleen become very soft, approaching to a state of solution.

"THORACIC CAVITY. — Hydro-thorax of the right pleuritic sac, containing 2½lb. of turbid and sanguineous fluid.

"No fluid in the left pleura, but a very extensive adhesion of the pulmonary pleura to the costal, and alteration of colour, it being *much too dark*.

"Left lung adhering very extensively to the costal pleura, of a livid colour, and friable; no crepitation on being cut, and almost without any vesicular appearance throughout the whole; merely a small portion of the superior part was permeable to the air, and that portion swam though the whole sank.

"Heart a little larger than the regular size, flaccid and discoloured, with some adhesion to the *posterior part*. The valves being examined, were found in the natural state. Further examination prevented by the necessity of preserving the heart entire.

"Kidneys altered, inclining to white, as also in the cortical substance, which was in a soft state. A calculus was found in the left kidney. In the bladder no alteration."

We have marked a few phrases and epithets, on which we have an observation or two to make. Of the production generally, we must repeat, that nothing of the kind can well be more

meagre. We are not informed how many hours elapsed before the examination was made. The date of the document, it is true, is the 25th September, the day after the royal patient's death; but, for aught we can learn, the autopsy might have taken place any time between twelve and thirty hours after. Nor is there a word said touching the external appearances of the body: no note is taken of the outward marks of the illness which produced death. It is not even mentioned whether there was anasarca of the extremities, or of the trunk—no unusual circumstance when the chest is in the condition here described.

The head, it would seem, was not examined: doubtless the physicians thought it unnecessary, as the intellectual faculties of the Ex-Emperor were unimpaired to the last. But, in an examination of this kind, made by authority, we think the omission rather inexcusable: it could have given very little additional trouble, and would have been more satisfactory to all parties.

In what we are told relative to the cavities examined, there are some things particularly deserving of notice. The omentum and peritoneum, it seems, were *rather too pale*; and no attempt is made to assign any probable cause of the phenomenon. Presuming that the words are correctly rendered, we only gather from this that the serous membranes of the abdomen were unnaturally pallid; but how can this accord with what follows—that those very membranes appeared to be "thickened by effusion of bile?" If *bile* had made its way into any portion of their texture, it is difficult to conceive how they should have been, at the same time, "rather too pale."

Concerning the stomach, we only learn one fact—that there was some discolouration of the mucous membrane in that part adjoining the spleen; the

latter viscous, as we are further informed, being almost in a state of decomposition.

The account of the lungs is dispatched with almost equal brevity; though here being the seat of the disease, a little more detail might have been expected. The abdominal cavity might, perhaps, be disposed of in a few words; but the chest, as containing the cause of death, one would think deserved a little closer inspection. We are not vouchsafed a single word respecting the right lung, any more than if no such organ ever existed. Where such a marked distinction was observable in the pleuritic cavities—one containing $2\frac{1}{2}$ lbs. of fluid, and the other none, it would have been at least satisfactory to learn in what state was the lung which was bathed in so much serous effusion; especially as such morbid appearances were noticed in the left lung, which seemed to be all disorganized, with the exception of a small part in its upper lobe.

Neither are the tidings of the heart more satisfactory: in the present day, when the morbid anatomy of that organ is so well understood (is it not so in Portugal?), what can we infer from being merely told that the heart was somewhat enlarged?—neither knowing whether there was hypertrophy or dilatation, if, indeed, there was any organic lesion about the parts. What is said of the adhesion of the heart is scarcely intelligible; perhaps the *pericardium* is understood, though not expressed: we should moreover expect to be told whether there was any effusion in the latter sac or not.

Altogether we must say that this *post-mortem* report, though signed by Don Joao Fernandes Tavares, first physician of the Royal Chamber, and by sundry surgeons, and other medical men of the Portuguese Court, with high-sounding titles, is not a very favourable exhibition of the state of pathological science in Portugal.

But if it be faulty as a mere report of morbid appearances, how must we qualify it when viewed in the light of a medico-legal document, concerning a royal personage?—for such it must be considered. The Duke of Braganza, it was rumoured, had fallen a victim to slow poison. No matter how vague or how absurd the rumour might be—and, indeed, it seldom happens that an exalted personage goes down into the tomb without giving rise to some suspicion of foul play—according to the poet's shrewd remark,

Ad generum Cereris sine cæde et vulnere pauci
Descendant reges, et sicca morte tyranni;—

however vague, we say, the suspicions might be in the present case, it surely behoved the medical attendants to give so minute and clear an account of what they were commissioned to observe, as to leave no room for any surmise.

What has been said in Lisbon, and repeated by a silly portion of the London press, respecting the cause of Don Pedro's death, is sufficiently ridiculous; it only claims our notice as confirming what we said last week of the manner in which all questions connected with science are dealt with by some of our daily contemporaries. The story alluded to is, that Don Pedro had been taken off by mixing poison in the water in which eggs for the royal table were boiled—some six months ago!

That such notions should still be formed touching the action of poisons—supposed to be secretly and mysteriously administered, brings us back full half a century in the history of medicine. We thought few educated persons were uninformed of the achievements effected of late years in chemical science with regard to this subject. But knowledge is certainly not *diffused*, nor does intellect *march* quite so rapidly as some philosophers suppose: the old leaven is hard to be worked off; and Dr. Christison perhaps takes too much for granted when he

says, that "partly on account of the improvement in general knowledge, and chiefly in consequence of the subtlety and precision which the refinements of modern physic and chemistry have introduced into medico-legal inquiries, it is rare that the suspicious scrutiny of the world now recognises in the accounts of the last illness of popes and princes, the effects of poison insidiously introduced into the body." "No one now seriously believes," says the same learned authority, "that Henry the Sixth was killed by a pair of poisoned gloves, or Pope Clement the Seventh by a poisoned torch carried before him in a procession, or Hercules by a poisoned robe, or that the operation of poisons can be so predetermined as to commence or prove fatal on a fixed day, and after the lapse of a definite and remote interval." Yet, what is too gross for the credulity of an age which holds out such encouragement for quackery? Time was when it was thought possible for a great personage to be carried off by the slow agency of a poisoned wig, a pinch of snuff, a medicated saddle, a perfumed *billet dour*, and the like: it remained for the present enlightened period to reverse the old adage—

Ora atque nuces tuto gustes;

and to give credence to an absurdity more rank than was ever heard of.

But let us hope that the "autopsy by authority," bad as it is, may tend, in some measure, to allay the inquietude of our good easy friends. A course of poisoned eggs would hardly have allowed the Emperor-Duke to escape so easily, and something more would have been visible in the stomach besides a discolouration such as that above described. And be it permitted us to add—whether our word be taken for it or not—that not all the poisons that Locusta or Toffana ever knew could have produced such a mass of chest disease as that through which Don Pedro died.

ST. GEORGE'S AND THE LANCET.

THE personal motives by which the Editor of the *Lancet* is influenced in his abuse of St. George's Hospital, are well known to all the medical world, and render any formal refutation of his absurd calumnies unnecessary. That he should be betrayed by his temper into a public display of the extent to which he suffers, is certainly not quite consistent with the cunning and worldly wisdom which he usually evinces; but we suppose there are some vexations which it is beyond human endurance to bear. With reference to the last ebullition of his rancour, we have received the following note—which, however, we trust will not lead to others of a similar nature, as the circumstances are too notorious to require any interference or explanation.

To the Editor of the Medical Gazette.

SIR,

It is stated in the last number of the *Lancet*, that all the medical officers attend, and that all the business is done here, at the same hour—viz. one o'clock. This is not the fact: every accommodation is afforded the pupils which the limited time intervening between lectures (viz. from half-past twelve till half-past two) permits. It is also said that no notice is given of post-mortem examinations!—whereas a card is always put up in the morning, and a bell rung before the autopsy begins. Further, at the end of the last Spring courses, the hours of visiting were arranged as follows:—Dr. Seymour, Tuesday, Thursday, and Saturday, at half-past 12; Dr. Macleod, Monday, Wednesday, and Friday, at a quarter before 12; and Dr. Wilson, same days, at one o'clock. Dr. Chambers was at that time prevented from attending by illness. Now this notice was put up in the hall and pupils' room, and remained there for many weeks.

I cannot conclude without adding, that the misrepresentations in the *Lancet* are so very gross, that I fear they are not unintentional.—I am, sir,

Your obedient servant,
A PHYSICIAN'S PUPIL.

St. George's Hospital, Oct. 6, 1834.

We have ascertained the correctness of the above, and, on second thoughts, would advise that if any of those concerned wish to stop Mr. Wakley's mouth, they should enclose him a "consideration," and promise *in future* to advertise their school on the wrapper of the *Lancet*.

CLINICAL LECTURES
ON
TYPHOID FEVER.

Delivered at the Hôtel Dieu, Paris,

By PROFESSOR CHOMEL.

Causes—Effects of Cold—of certain Periods of Life—of Residence in Cities.—Doctrine of Contagion—Opinions of various French and English Physicians.

THE causes of typhoid fever are enveloped in great obscurity. We know well some of the circumstances which predispose to it, but the exciting cause—that by the action of which it is immediately produced—escapes all our investigation. This obscurity as to the exciting cause is not peculiar to typhoid fever; it also exists in respect to most other internal maladies; and, indeed, we in general adopt with too much confidence the set of causes to which diseases are attributed, and which are almost always the same for affections the most different. If we take, for example, inflammation of the lungs, one of the diseases in all respects best known, we find a great degree of obscurity in the causes which produce it. The only thing which we know with certainty respecting the etiology of pneumonia, is that it is most frequent in cold seasons; beyond that all is hypothesis. Every day it is attributed to the direct action of cold upon the frame; but the same circumstance is far from always producing the same effect. A thousand times has the same individual, who to day is attacked with pneumonia from cold, been exposed to greater cold in similar circumstances, and yet this same cause has never before produced such an effect. In the same way it is in vain we seek, in most cases, for the cause which has produced erysipelas, or pleurisy, or peritonitis. We see very well some of the conditions under the influence of which the disease supervenes, but those which actually produce it constantly escape us;—in this respect typhoid fever ought not to be separated from most diseases called internal. There is, however, this difference between typhoid fever and some of the inflammations above mentioned, inasmuch as the latter may be artificially produced, by injecting irritating substances into the cavities. But in the present state of our knowledge, we cannot at will produce that alteration in the glands of Peyer which we see in typhoid fever. One exciting cause is alone admitted by some, namely, contagion; but this is generally denied; and as the mode of transmission, supposing contagion to exist, always escapes us, and as the obscurity which hangs over the first exciting cause is the same whether we admit or deny contagion, we are not less in igno-

rance of the nature of this cause, and of its mode of action.

The predisposing causes of typhoid fever have been the object of particular research, and have led to tolerably positive results. Too often, however, we have been guided, in seeking for the causes, by theory rather than observation; the nature of the disease has generally been first determined, and a knowledge of the causes subsequently obtained; whence it has followed that the causes acknowledged to have produced the disease have been influenced by the ideas which we had previously adopted respecting the nature of the disease itself. Thus, those who attributed all these fevers to a putrescent alteration of the fluids, necessarily admitted as causes every thing which produced debility, or which favoured putridity: poverty, abundant hæmorrhages, fatigue, mental distress, acting upon those who inhabited badly-ventilated localities, prisons, barracks, hospitals, &c. But a still more curious fact connected with the natural direction of the mind, and which shows well the influence of theory, is the error into which those have fallen who have considered persons advanced in life as more disposed than the young to typhoid fever; although it is well made out that we never meet with it in old persons. Such pathologists, regarding fever as produced by weakness, concluded, *à priori*, that it was most frequent amongst the aged. On the other hand, the physiologists, setting off with the idea that all febrile diseases were inflammations of the alimentary canal, have necessarily considered every thing which irritated the stomach and bowels as among the causes of fever. The following table, taken from 115 instances of typhoid fever, in which the intelligence of the patients enabled exact information to be obtained respecting the causes to which the disease was to be attributed, goes to show how erroneous the ideas are which are generally admitted regarding the etiology of this disease.

- 5 attributed their complaint to cold applied when they were very warm.
- 5 to the absence or bad quality of nourishment.
- 1 to depressing moral affections.
- 5 to the debility produced by preceding diseases.
- 3 to the action of purgative medicine.
- 1 to excess in spirituous liquors.
- 5 to excessive fatigue.
- 2 to violent physical "commotion."
- 1 to exposure to the sun.
- 5 related circumstances favourable to contagion.
- 79 could assign no appreciable cause,

Thus scarcely one-fourth attributed the disease to any cause of the least energy. One cannot but be struck, too, with the small number in which the disease could be attributed to circumstances connected with the alimentary canal; and even with regard to this, it is probable that the indisposition for which they took the purgatives was in reality the commencement of the typhoid fever. If we compare the above with the cases of pneumonia observed in a number nearly equal, and which occurred at the same time, we shall have another proof of the little influence of circumstances which are considered of importance in the etiology of internal diseases.

Of 137 cases of inflammation of the lungs,

28 attributed the attack to the influence of cold.

24 to the consequences of catarrh.

6 to violent labour without cold.

4 to the abuse of spirituous liquors.

3 to the influence of amenorrhœa.

1 to the puerperal state.

1 to the consequence of bruises.

68 could assign no cause.

A comparison of this table with the preceding will exhibit some interesting points in the etiology of fever. First, we may remark how few, comparatively to the general opinion, is the number of cases in which pneumonia is attributable to the action of cold, and how considerable, on the contrary, those in which the real exciting cause was not apparent. However, it is difficult, even from this table, to refuse to acknowledge, in the etiology of pneumonia, the action of some occasional causes which are not found in typhoid affections. Thus the number 28, pointing out those attributing their pneumonia to the action of cold applied when they were hot, is too great to be considered as accidental; and we cannot doubt that the cold had really an influence in producing the disease. We do not find among the cases of typhus any thing which can warrant us in drawing the same inference. There is evidently something in the etiology of typhoid fever which we do not find in that of any of the inflammations among which it has been attempted to class it; for the same results would have been obtained had we compared it with peritonitis, or any other of the phlegmasia.

Besides the differences just alluded to, there are some conditions in which the typhoid affection is developed, and which are peculiar to this disease. The study of these conditions is one of the most important, and at the same time most positive, in the etiology of the disease. I shall speak of these in succession, begin-

ing with the age at which the disease is developed. In 117 patients—

8 were from 15 to 18 years of age.

25 18 .. 20

36 20 .. 25

30 25 .. 30

9 30 .. 35

3 35 .. 40

5 40 .. 50

1 0 .. 52

If we compare this table with the results obtained by M. Louis and others, we shall perceive that the most frequent period of attack is from 18 to 30; that it is rarely seen above 40; and that, perhaps, no case has been met with where the patient was above 25. It is therefore at that period of life during which the strength is most developed, that typhoid fever is most frequent. It is in vain that we endeavour to explain the cause of this, which we are no more able to discover than why measles, small pox, and scarlatina, make their attacks principally in infancy.

Another condition which modifies the development of typhoid fever is residence in a large city. The number of patients whom we receive with this disease into the hospitals are such as have been a short time in Paris. The following table shows the influence of this circumstance in 92 patients.

5 had resided in Paris somewhat less than a month.

10 from 1 to 3 months.

9 from 3 to 6 months.

21 from 6 months to a year.

19 from 1 year to 2.

15 from 2 to 6.

11 upwards of 7 years.

2 had been born in Paris.

—

92

It appears from this table that more than two-thirds had been in Paris for less than two years; but while the influence of acclimatization is thus demonstrated, we cannot, in the present state of our knowledge, offer any positive explanation of it.

Those who regard typhus as contagious easily explain, according to their opinion, why persons coming from the country, where the disease does not prevail, become more liable to it in large cities, where it is always to be found. This leads us to one of the most important questions in the etiology of the disease, namely, its transmission from one person to another. Some—and in France at least they constitute the majority—reject contagion altogether; but as here we ought rather to weigh the reasons than count the numbers, and as, besides, the

doctrine of contagion has many partizans in other countries, we shall examine the arguments on both sides. We shall commence with those which the non-contagionists cite in favour of their doctrine.

1. We see every day persons nurse patients labouring under typhus, and who nevertheless escape, although many of them are evidently placed under the most favourable circumstances for contracting the disease.

2. There is not a single bed in the hospital in which some individual affected with typhus has not lain, and it is uncommon not to have several cases of the disease in each ward; notwithstanding which we do not see that the patients adjacent to them—that those who assist them, or even who sleep on the same mattress, and cover themselves with the same bed-clothes, become affected with the fever.

3. Sometimes, indeed, we see an individual received into the hospital for some other disease, become affected with typhus; but these cases are so exceedingly rare, that only one or two such have been observed in the course of many years, either at the Hôtel Dieu or La Charité; and they certainly shew nothing in favour of contagion, because it cannot be supposed that individuals admitted into hospitals are beyond the reach of the causes which produce the disease. It must be confessed, however, that it is only from observations made in great cities, as in Paris, that the proofs (proofs, by the way, which are but negative) are derived; and it is not in such a field that the question can be determined. M. Bretonneau, who was the first in France to call the attention of practitioners to the contagion of this disease, has made numerous valuable observations on its transmission in villages and small towns. He was able to follow it, step by step, as it passed from one locality to another, and saw it communicated from an affected family, not to those who were nearest, but to those who had the most frequent and intimate connexion with the sick; and in this view of the case he is supported by several practitioners of the highest respectability.

We may add to these facts, which have been collected in Paris, or other parts of France, those accumulated by the English physicians: and first, it would appear that examples of transmission of typhus are as rare in the London hospitals as in those of Paris; and Dr. Elliotson, who admits the contagion of the disease, and who has been long one of the physicians to St. Thomas's, affirms, in the *London Medical Gazette* (vol. x. p. 146), that he has never observed in the hospital a single instance of contagion. It is different, however, in the Fever Hospital; as we

find by the report of Dr. Tweedie; who states, that since its foundation, in 1802, all the physicians, with one exception, (that of Dr. Bateman,) have been attacked with fever, and that three out of eight have died with it. He adds, that all the resident officers—whether medical, matrons, nurses, porters, washerwomen, and other domestics—have, without exception, been attacked with the fever. This would seem to prove that the disease may be communicated by the linen which patients have used; for the washerwomen do not require to enter the wards. The adversaries of contagion, who cannot deny these facts, endeavour to explain them by the situation of the hospital; to which it is answered, by Dr. Tweedie, that nothing similar occurs in the Small-pox Hospital, which is close by it.

But it is not at the Fever Hospital of London alone that facts favourable to contagion have been observed. In 1817, the increase of fever in Edinburgh induced the government to open an hospital destined for fever patients. Queensbury House, a building in a healthy situation, and in the neighbourhood of which there were but few cases of the disease, was chosen for the purpose; nevertheless, all the resident pupils, and all the nurses, were successively attacked with the fever. This hospital having been shut up, was not again re-opened until 1826, when the resident physician, the apothecary, several servants, and all the nurses, with the exception of two, took the fever. During the same epidemic, six pupils and twenty-five nurses took the disease in the Royal Infirmary of the same town. At the Fever Hospital in Dublin, where also the distemper raged, fifty-two nurses out of fifty-seven suffered from it. We also find, in the memoir of Dr. Marsh, numerous facts in support of contagion; among which there are twenty-two instances which it is difficult to get over. Among these last are seven medical men, including the author of the memoir. These facts, borrowed from the English physicians, would be still more valuable if it was demonstrated that the disease to which they relate was exactly the same as that which we have been occupied in considering, and that the affection which the English denote generally under the name of *fever*, did not on some occasions assume the characters which belong to *camp fever*; and, indeed, another point which favours the doctrine of contagion, is the analogy which exists between the *typhoid* affection, and the *typhus* which prevails in camps; the contagious nature of which no one doubts.

I have thus presented with the utmost impartiality all the arguments for and

against contagion in typhoid fever, and the following are the conclusions at which I have arrived. 1st. The opinion adopted by the greater part of French physicians, that typhoid fever is not contagious, cannot be regarded as demonstrated. 2dly. If this disease be contagious, it only is so in a small degree, and requiring the concurrence of circumstances as yet but ill ascertained. 3dly. If further observation shall demonstrate, in typhus, the same anatomical lesions which are met with in typhoid fever, the identity of the two affections would be placed beyond a doubt, and the question of contagion set at rest.

The present state of our knowledge on this question does not admit of our entering upon the consideration of certain points connected with the doctrine of contagion. Thus I shall not stop to inquire into the mode of transmission of typhus fever, or into the circumstances which favour it. These questions, which would be of great interest if contagion were demonstrated, are not worth discussing till this uncertainty be removed.

CASES OF PARALYSIS OF INDIVIDUAL NERVES OF THE FACE.

BY DR. CHRISTISON.

CASE I.—Palsy of the Third Nerve or Motor Oculi—Recovery under free Venesection and Mercurial Salivation.

A stout blacksmith, of middle age, and much given to drinking, was admitted into the Fever-hospital, supposed to labour under continued fever. During the confusion incident upon opening the hospital, and receiving a great number of patients before the appointment of a physician, the exact nature of his case was for some days overlooked; but a day or two after my appointment, my attention was called by Dr. W. Reid, then superintendent of the hospital, to a considerable squint of the left eye; upon which the following account was given by the patient.

Three weeks before his admission into the hospital, and immediately after a debauch, he first remarked that he saw double; and at the same time he was affected with ringing in the ears, headache, and giddiness, which last symptom was particularly troublesome when he kept his left eye open. After a fortnight he had rigors, general soreness, and increase of headache; and for ten days after admission into the fever-hospital, he had

the symptoms of a mild attack of general fever, with continuance of double vision. Subsequently the two images gradually approached one another, till at length they coincided, and he saw single; and at the same time the general fever ceased. When first carefully examined, a few days after that, it was observed that the left eye-ball was turned very much outwards; that he had no power whatever to turn it upwards, inwards, or downwards; that when desired to look up, he merely rotated the eye-ball on its horizontal axis inwards; and that the upper eye-lid always hung over the ball, so as to be in contact with the lower, except when he was told to raise it, upon which he uncovered half only of the pupil. The pupils were equal in size, and contractile; and when he closed either eye, he saw quite well with the other. The vision with both eyes was not double. He had frequent diffuse headache, but no disorder in any other function.

For some days after this examination, the state of the affected eye varied, as he occasionally recovered imperfectly the movements of the eye-ball for twenty-four hours at a time; but at length they were lost entirely. The treatment for ten days after the paralytic affection was remarked consisted in the occasional application of leeches to the temple, and of a blister issue behind the ears, together with frequent laxatives. No amendment, however, was procured from these measures.

Four or five days later, when he had been three weeks in the hospital, his headache began gradually to increase, and the pulse to rise; in a day or two more he complained of great general soreness of the head, and of shooting pains, numbness, and diminution of muscular power in both limbs. Blood was therefore drawn from the arm, to the amount of two pounds. It was very buffy, and gave immediate relief from the headache. Calomel was also prescribed, in the dose of five grains four times a-day, with a little opium, for the purpose of quickly affecting the mouth. When this had been continued four days, the affection of the limbs ceased, and the fever abated considerably; but a slight deviation was remarked in the tongue, to the left, and in the mouth, towards the right side; while at the same time the affected eye was turned more outwards than ever. On the sixth day of the mercurial treatment his gums became tender, and the calomel was therefore discontinued. A moderate salivation immediately followed. On the fourth day after the discontinuance of the calomel, there was an obvious improvement in the state of the eye, and in twenty-four hours more the improvement was considerable. The movements of

elevation, depression, and adduction of the eye-ball, could be performed to half the natural extent, and he could raise the eye-lid so as to uncover two thirds of the cornea. At the same time the deviation of the tongue and mouth, the headache, and all his complaints, ceased.

From this time he improved rapidly and steadily, so that in a week after the lost movements recommenced they could be performed perfectly. The salivation lasted twelve days, and was always gentle. In twelve days more he was dismissed quite well, having been in the hospital seven weeks.

It is worthy of remark, that after the movements of the affected eye returned so completely, that this eye, when the other was covered, could follow a moving object briskly in any direction, some days more elapsed before the affected eye accompanied the other in its movements, when both were uncovered. For example, if the patient was directed to look at an object straight before him, he squinted the left eye outwards, and looked at it with the right only; but if he was told to look at it while the right was covered, he turned the left on it; and when the right was then uncovered, he directed both eyes on the object, and for a few seconds followed it with both, when it was moved before him.

I shall not attempt to explain the singular fact mentioned at the commencement of the case, as to the man first seeing double, and then remarking a gradual approximation of the two figures till they coalesced, and he saw single, — while the squinting of the eye nevertheless continued. This is so different a phenomenon from what we should expect in the circumstances, that I shall not insist on the accuracy of the statement, because it was drawn up from the man's own account of what occurred some days before I saw him. Yet it is fair to add, that he always gave a very clear narrative of the progress of his illness, and never deviated in any particular from his first statements. In such a case, we should expect—not that the images would gradually approach and coalesce—but simply that the individual would gradually acquire the habit of abstracting his attention from one of the images, and so recover single vision.

CASE II.—*Palsy of the Portio Dura of the Seventh Nerve on both sides.*

A young man, of middle stature, was admitted into the Fever-hospital on account of a smart attack of continued fever of the inflammatory type, but without any particular local inflammation. On the fourteenth day of the disease he got quickly better by critical sweating, the

pulse falling from 120 to 72 in the course of a single night. Nothing occurred to interrupt convalescence till the end of the fourth week, when he complained of a sore mouth, for which a vinegar wash was ordered. In five days more, however, the man continuing still to complain of his mouth, a careful examination was made, when the dead stillness of his countenance at once attracted attention. The lips were completely palsied, and could not be closely shut, the nostrils could not be curled, the upper eye-lids could not be closed, and he could neither laugh nor whistle. At the same time the sensation of the affected parts was every where perfectly entire. He had not the slightest fever, no headache or local pain of any kind, except soreness of the mouth; and his only complaint, indeed, was of the dryness and soreness of his lips.

Low diet was ordered, blisters were applied behind the ears, and leeches immediately before them, and laxatives were frequently administered; but without the slightest advantage. About this time the last patient, with palsy of the *motor oculi*, recovered apparently under the operation of mercury. The same treatment was therefore applied in the present instance, and a smart salivation was brought on, which terminated in a copious impetiginous eruption over the whole face. The patient, however, did not derive the slightest benefit. All the parts supplied by the muscular portion of the seventh nerve, on each side of the face, continued in a state of perfect paralysis. After remaining three months in the hospital he was dismissed in the same condition; and I have never since been able to receive any information of the progress of his disease.

CASE III.—*Paralysis of the Portio Dura of the Seventh Nerve of the Right Side.*

When in the country last autumn, I was requested to visit a young man who was supposed to labour under palsy. His paralytic affection was of five or six days' standing; and it was preceded for some days by severe aching pain in the whole right side of the face. When I saw him the pain had ceased; but the whole right side of his face was completely paralyzed. In a state of repose it did not present any peculiar appearance, except considerable depression of the right eye-brow. But on careful examination I found that he was unable to whistle, to curl up the right side of the nose, to elevate the right eye-brow, or to close the right eye-lid; and when he laughed the mouth was drawn much to the left side. The right eye watered a good deal; and when told to close it, he closed the lids imperfectly, and turned the pupil upwards beneath the upper eye-lid.

He complained of acute pain on pressure upon the cheek in the region of the exit of the infra orbitary nerve, and likewise in the jaw at the exit of the inferior maxillary nerve upon the chin, also of *tin-itus aurium* when at work. He had never had headache, or any pain or swelling before or around the ear; neither was there ever any weakness of the limbs or arms, any material difficulty in speaking, or divergence of the tongue from the straight position when thrust out. The sensation of the cheek, too, was quite entire. The pulse was natural.

I recommended him to have a blister applied frequently before and under the right ear; and after following this plan of treatment to resort to a mild course of mercury if he was not relieved. Six blisters were in consequence successively applied between the close of September and beginning of December; and during the latter part of that period mercury was given so as just to affect the mouth.

Some amendment was remarked after the application of the last blister, which extended from behind the ear to the chin, and acted very severely. Till then he experienced no improvement, and since then he has made but little progress. I am unable to state the precise amount of amelioration that has taken place; but I have been informed by the clergyman of his parish, that he can now close the right eyelids completely, but does so very slowly,—that the other palsied actions of the muscles of the face appear to remain nearly as when I saw him,—and that he has still acute pain on pressure on the cheek under the eye, or on the lower jaw near the chin,—but that he continues entirely free of general palsy, or any head symptom.

Aug. 18th, 1834.—The patient eventually got quite well.

CASE IV.—*Palsy of the Optic Nerve (?)*

The next case to be mentioned I have entitled palsy of the optic nerve; although I believe the propriety of the name is doubtful.

A middle-aged man, of meagre habit, and very deeply scarred with small-pox, was admitted in the summer of 1829 into the surgical department of the Infirmary, on account of chancres and bubo. The chancres soon healed; but the sore left in the groin after the suppuration and opening of the bubo was untractable. While in this state, he was attacked with dysentery, which at that time (Autumn 1829) prevailed in the hospital, and was so fatal that about a fourth of those who were taken ill perished. Being transferred to the medical department on account of the dysenteric attack, he became my patient. At this time he had dysentery in its worst

form; and although the acute stage was soon subdued, the symptoms nevertheless shewed that extensive ulceration had taken place in the intestines; and he died six weeks after I saw him.

At first no attention was paid to the circumstance of his being blind of an eye, as the marks of severe confluent small-pox seemed to account for it sufficiently. But on his mentioning to me incidentally, that the sight was lost only two years before, careful inquiry was made; and it was then learned, that, on the occasion alluded to, he had been a patient in St. Bartholomew's Hospital, London, with severe headache, giddiness, feverishness, and incomplete palsy of one of his sides; and that he gradually got the better of these symptoms, but was at the same time attacked with inflammation of the left eye, which burst, and became totally blind.

It was natural in these circumstances to expect that some injury would be found in the course of the fifth nerve. This nerve, however, was found quite healthy, so far as the sight and touch could determine. But the optic nerve of the affected side, between its exit through the orbit and its decussation with the opposite nerve, was not more than half the breadth of the other, and was grey in colour, and flaccid in texture. Between the point of decussation and the thalamus of the opposite side it was of the natural whiteness, but softer and less than its fellow; and the thalamus itself was somewhat flattened. The brain was otherwise healthy, except that a very great watery effusion had taken place under the arachnoid coat over the whole external surface, which appeared to account for the severe headache and frequent incoherence remarked towards the end of his illness. There was no appearance of an old cyst or other disorder in the substance of the brain. The colon was covered to an enormous extent with ulcers in various stages of progress. The left eye was completely disorganized.

I am quite aware that, in calling this case palsy of the optic nerve, I may err in taking for the cause of the destruction of the eye what was really its effect. Neither do I pretend to say that there is much probability in the view here given. But it appears to me right to make known the particulars, because it is not impossible that diseases of other parts of the nervous system, besides the fifth nerve, may lead to destruction of the eye; and this is presumptively a case of the kind, the presumption being founded on the bursting of the eye having been immediately preceded by some organic disease of the brain, and being not associated, as usual, with disease of the fifth nerve.—*Edin. Med. and Surgical Journal.*

ST. GEORGE'S HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

IF you would allow me to record, from time to time, in the pages of your journal, some of the cases which are brought before my attention and that of my fellow pupils, at St. George's, I think I could relate some that would prove interesting to the senior members of our profession, as well as to those of my own standing.

In relating this case, I have taken care to separate facts from conjecture; so that your readers may draw conclusions for themselves.—I remain, sir,

Yours obediently,

A PUPIL OF ST. GEORGE'S
HOSPITAL*.

Oct. 7, 1834.

*Case of Disease of the Pineal Gland (?), with
Remarks.*

Matilda Kendal, æt. 21, admitted June 11th, under the care of Dr. Macleod. Complaints of a severe pain in the back part of the head, extending down the nape of the neck. There is no tenderness on pressure, nor any thing preternatural to be observed externally. She feels much general oppression, her nights are sleepless, and there is great debility. The eye-sight is impaired; pulse 80, soft, of good strength; skin cool and moist; tongue loaded in the middle, red at tip and edges; bowels confined, it being a week since they had acted last. Some thirst; no appetite; urine natural; catamenia absent for two months.

About six weeks ago she caught a very severe cold, accompanied by cough, which continued for some time. The pain above-described supervened upon this, and on the subsidence of the cold still continued, having become more and more severe, up to the period of her admission. The following medicines were prescribed:—

Subm. Hyd. gr. iij. h. s.; Haust. Sennæ cras mane; Haust. Salin. ʒiiss. 6tis horis. Fever diet.

12th.—Bowels freely purged; in other respects as before.

Rep. Medicamenta pro re nata. Emplastr. Lyttæ Nuchæ.

20th.—She experienced some slight amendment in her general feelings for the first two or three days after the above treatment was adopted, but the pain in the head does not seem to have been at all relieved. A fluttering convulsive move-

ment has been observed for some days in the sterno-cleido mastoid muscles, particularly on the left side. Answers questions in a sharp altered tone.

Applic. Hirud. xx. nuchæ.; Calomel-gr. v. hac et crast. nocte; Haust. Sennæ, quamprimum et cras. mane.

23d.—The leeches afforded no relief. Has been observed, from an early hour this morning, to sit up in bed, with her head bent forward upon the knees and her hands grasped across the occiput. States that the attempt to raise the head gives her violent pain in the back of head and neck. Bowels freely purged; pulse 90, soft; tongue white and loaded; considerable thirst; appetite improving.

Cucurh. cruent. Nuchæ ad ʒxiv. Head to be shaved, and spirit lotion to be kept constantly applied to it. Cal. gr. v. 6tis horis.

27th.—Symptoms have continued unabated, and with little change, except that she has had an attack of spasmodic twitching of the right arm to-day.

30th.—Continues to complain of the pain in the back part of head; which, she says, has been in no degree relieved by any of the remedies employed. Head still bent forward upon the knees; mouth a little tender from the mercury; tongue patched, the crust peeling off in irregular portions. Vomited for the first time. Bowels open; urine rather scanty; pulse 112, small; skin cool.

Rep. Calomel, bis die; Haust. Sennæ quotidie mane.

July 4th.—Mouth sore; pain in head and neck very much relieved; sight better; spasmodic action in muscles has entirely ceased; slept well last night, having been able to lie down in bed without aggravating the pain.

On the following day, the report says, "began to complain, during the night, of a recurrence of the pain; head bent forward as before; some appearance of aphthæ about the edge of tongue; less pytalism."

Hirud. xx. occipiti; Rep. Med.

7th.—The leeches afforded no relief; on placing her in the recumbent posture for a few moments to day, she screamed from the aggravation of suffering.

Empl. Lytta occipiti; curatur ulcus ung. Hydrag. Rep. Med.

11th.—No better; expression of countenance vacant; some deafness; strabismus; the pupils contract, but sluggishly, before the light of a candle.

14th.—Partial stupor. The contents of rectum and bladder came away to-day unconsciously.

* We have inserted the following case with pleasure, the writer having authenticated it by sending us his name; and we shall be happy to hear again from our new correspondent.—E. G.

Calomel, gr. iij.; Digital. gr. j. M. fiat pil. 6tis horis sumenda.

16th.—Insensibility deepening, and accompanied by jactitation.

From this period she became gradually worse, having occasional fits of perfect stupor, and passing dark offensive evacuations from the bowels. She was then seized with vomiting of green liquid matter, and died on the 20th, emaciated to the last degree.

Post mortem examination.—On removing the skull-cap the dura-mater near the longitudinal sinus was found firmly adhering to the subjacent surface. All the vessels of the brain were loaded with blood. Immediately beneath the fornx, lying on the nates and testes, and projecting between the thalami into the third ventricle, a tumor was discovered of the size of a large walnut, and composed apparently of coagulated blood, with embedded portions of brain-like matter pretty thickly interspersed. The brain in the vicinity of the tumor was softened, but no other lesion was discovered.

Observations.—Almost from the very first it was suspected that a slowly-growing tumor in the brain was the cause of this girl's constant and severe suffering; but the most favourable view that could be taken of the case was to suppose that there was effusion only. The indication to be followed, therefore, was to stimulate the absorbents, and thus, if possible, to remove the fluid.

Local bleeding having been premised, and counter-irritation set up, with a view to the abatement of any inflammatory action there might be in the brain, mercury was exhibited, to the extent of affecting the mouth; and it was singular to observe how close upon the salivation improvement followed. The beneficial effect of remedies, however, was soon overpowered by the inherent tendency of the disease to become aggravated; and symptoms such as usually proceed from slowly increasing pressure on the brain, made their appearance, accompanied by others that are not so commonly observed.

The most striking features of this case were the singular attitude, which, for a long time, was alone supportable, and the peculiar shrill tones in which the patient made known her wants. I need not remark, that a voice, subdued in proportion to the severity of the disorder, is what is ordinarily heard from patients, at least while the mental faculties are retained; but in this case, notwithstanding the extreme exhaustion of the sufferer, her shrill tones could be heard in any part of a long ward; and I cannot but think there was some connexion between the character of her voice and the nature of her complaint.

The position which she assumed tended to throw the whole weight of the brain upon the anterior part of the skull; and this, viewed in connexion with the post-mortem discoveries, affords some explanation, I imagine, of the comparative relief she experienced from the seemingly uncomfortable posture she maintained day and night; the effect being to relieve the parts supporting the tumor, viz. principally, the nates and testes, from the additional burthen of the cerebral mass generally.

Relief having been afforded, though but temporarily, by the calomel, when that passed off, it was attempted to combine with it some other medicine that should act with increased force upon the absorbent system. The combination, therefore, of calomel and digitalis was prescribed, though little hope was entertained that much benefit would be derived from any plan of treatment. The disease in the brain, whatever it might be, with a slight intermission only, had continued to increase from the period of the patient's admission into the hospital; the almost constant pain being a sufficient indication of this fact: but at length the brain, from the effects of increased pressure, ceased to indicate the progress of the disorder by the last-named symptom, and partial coma followed; the eye-sight and hearing having previously been affected, the sense of touch soon became impaired, and the controul over the rectum and bladder lost.

On reflecting on the circumstances of this case, and especially calling to mind the appearances after death, I am strongly inclined to believe that the tumor discovered was a malignant enlargement of the pineal gland.

GUY'S HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

BELIEVING that a brief account of the operations performed at this hospital in the course of the week, would be suitable for your excellent and most esteemed weekly periodical, I take the liberty of sending them to you for insertion.—I am, sir,

Your obedient servant,

A PUPIL.

October 7, 1834.

Recent Operations.

It having been posted up in the hospital this morning, that "several operations" would take place; and it being the first day for operating in the theatre since the arrival of students at this hospital for the session; at one o'clock (the hour appointed

for operating) the theatre was crowded to oppression—even to overflowing. The inconvenience of the smallness of the place, and the practice of suffering dressers to station themselves immediately between the patient and pupils, was at this time particularly evident. The first patient who was brought into the theatre to be operated upon, was under Mr. Morgan's care: a man who had for a considerable time suffered from disease of the tarsus. The foot was amputated by Mr. M., with the common circular incision. Spasmodic action of the muscles of the leg was very considerable during the operation.

A tumor was afterwards removed from the shoulder of a female, by Mr. Aston Key: it appeared to be of the steatomatous nature, and was of considerable size.

Another patient was then brought in, to submit to amputation at the thigh, for extensive disease of the cartilages and other structures of the knee-joint. She was a young girl, whose health had been lately sinking under the constitutional irritation which had been induced by the disease. Mr. B. Cooper performed the operation with much neatness, making a double flap.

A boy next walked in, with a tumor which was situated on the back: this was quickly removed by Mr. Morgan.

The last case was that of a poor fellow, aged about 50, who was to have his penis amputated, for a malignant disease which affected the extremity. A fillet was passed around the penis at its root, to restrain hæmorrhage, and the penis was likewise extended by an assistant laying hold of it at the extremity; the patient being in the semi-erect position. Mr. Morgan, with one stroke of an amputating knife, separated the unhealthy from the healthy part, which latter portion was extremely swollen; the arteria dorsalis penis, and arteries of the corpora cavernosa, were secured by ligatures. A gum-elastic catheter was then passed, and left in the urethra. The wound was dressed with a pledget of lint.

DISEASES OF THE CHEST,

In the course of which the Application of
PERCUSSION AND AUSCULTATION
ARE FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE III.

THEORY OF THE SIGNS OF DISEASES
OF THE LUNGS—(continued.)

PERCUSSION.

WE now proceed to the subject of Percussion.

The diseases of the chest were involved in great obscurity from the earliest periods of medicine up to the middle of the last century. The reason of this appears obvious. In the first place, the lesions of the particular textures which enter into the composition of the lungs and heart, were not then well understood. An acquaintance with morbid anatomy in general had not arrived at the point which it has attained at the present day; and it follows as a matter of necessity that if these morbid lesions were not known, neither could the signs be to which they gave rise. We have been too much, also, in the habit of satisfying ourselves with the study of signs alone, and considering them as diseases, instead of reflecting upon the alterations of structure which give origin to them. Thus we find that Cullen has established a genus which he calls *dyspnœa*. Now difficulty of breathing is only a sign of a particular condition or conditions of the chest, and is not a disease: it is the internal cause which produces the dyspnœa that is really the disease. Thus, again, Cullen and other authors have defined

asthma to be a difficulty of breathing occurring at intervals, without fever; but this, which they call a disease, is merely a sign, and a sign depending upon various causes.

Bichât, by his views of general anatomy, gave a new impulse to the study of morbid anatomy. He, from a hint given by Pinel, no longer regarded an organ as a homogeneous structure, but as composed of a variety of different tissues. He analyzed these tissues, and pointed out that they were subject to different physiological and pathological laws. Since that period morbid anatomists have taken the same view, and followed up their investigations according to the same principles. They have unravelled (if I may so express myself) the diseases of the various elementary structures of a viscus, and have shewn them in their isolated and combined states. To take an example from the lungs, we have here an organ which does not consist of a homogeneous structure, but of air tubes formed of cartilage and mucous membrane, &c.; of cellular tissue and vesicles, of blood vessels, of nerves, and, finally, of a serous membrane, which envelopes the whole. All these have diseases peculiar to themselves, which may exist in an isolated or combined manner: thus we may have pleuritis without catarrh, and *vice versâ*. As we proceed we shall have constantly-recurring evidence of these facts. Morbid anatomy is advancing most rapidly, and consequently affections of the chest, like other diseases of the body, are really becoming better known.

In the next place, diseases of the chest were not understood, on account of the equivocal nature of their signs. *Dyspnœa*, a great and leading sign of these affections, is equivocal, inasmuch as it is common to every disease, both of the lungs and the heart, when it has reached to a certain point; and it also occurs in some diseases external to the thoracic cavity. Cough,

too, is equally equivocal, for it may occur in all diseases of the chest, and even in some abdominal disorders; nor is the violence of a cough any proof of the gravity of the disorder, as the severest may happen from comparatively trifling affections, as a slight inflammation attacking the larynx, whilst the lung may be profoundly lesed, as in peripneumonia, and cough may be absent.

There can be no doubt that the inadequacy of these signs to determine any specific disease first led Avenbrugger to think of percussing the chest. But, before I speak of his discovery, I will mention a few particulars relating to himself. Leopold Avenbrugger, or Awenbrugger, was born at Grats, in Styria, in 1722: he became physician to the imperial hospital of the Spanish nation at Vienna. There it was, as he expresses it, *inter lædia et labores*, that he prosecuted his studies on this subject for a period of seven years; and in the year 1763 he published a work which he called "*Inventum novum ex Percussione Thoracis humani, ut signo, abstrusos interni pectoris morbos detegendi.*" No notice whatever was taken of his book until the year 1770, when Rozière de la Chassagne, of Montpellier, translated it, avowing he knew nothing of the subject practically; and the inference which he would lead you to draw is, that he did not think much of the discovery himself. The pamphlet seemed now consigned to oblivion: however Stoll, Van Swieten, and Cullen, in his *First Lines*, make some mention of it; but, like Rozière de la Chassagne, declared they knew nothing of it practically. Corvisart, when preparing his celebrated clinical lectures, first met with the subject in reading Stoll's work. He immediately commenced a series of experiments, which he continued for twenty years; and in 1808 he published a new translation of Avenbrugger, with his own commentaries; a work that has been translated, I believe, into every European language.

Principle upon which percussion depends—

Let us, in the first place, speak of the principle upon which percussion depends. Suppose a hollow ball, or a vessel of any kind, made of wood, glass, metal, or any other material, and containing atmospheric air only: strike it with the finger, and a certain sound will be produced, varying, of course, in kind and intensity, according to the size of the vessel, the nature of its parietes, and their thickness. Half fill this vessel either with a fluid or solid matter, percuss it, and there will be a difference in the sound. The sound will be duller than it was before; and the lower part, containing the fluid or solid, will be duller than the upper, which contains air

only. Fill the vessel completely, and the sound of course will be duller than in the first instance. This is so perfectly obvious that no experiments can be necessary to prove it.

What is the human chest? It is a hollow cavity, containing within it two organs; the one solid, at least so far as regards percussion—the heart; and the other the lungs, an organ containing a quantity of atmospheric air. Hence the chest will give a louder sound in the healthy state, on percussing it, than any other part of the body.

Before we proceed to elicit the various sounds which may be produced by the percussion of the chest in the living subject, let us first describe some preliminary steps relative to the position of the patient, &c.

Position of the patient.—It is best to place the patient in a chair with a wooden seat: if, however, he be in bed, let the curtains be widely opened, that the sound be as little deadened as possible. The chest may be examined in reference to its anterior, lateral, and posterior regions. If the anterior, the head and shoulders should be thrown well back, and the arms brought behind the chair: in this manner the pectoral muscles are put upon the stretch, and a better sound is produced. If the lateral region is to be examined, the body should be inclined to one side, and the arm passed over the head, and then percussion is easily performed from the highest point of the axilla to the lowest rib: if the posterior region, let the patient fold his arms, incline his shoulders inwards, and his head forwards; the muscles of the back will thus be rendered tense and firm, and the sounds may then be easily obtained.

You will observe that the objects we have in view in these positions are to place the patient in a convenient posture for the operator, and to render the external parietes of the chest of the patient as firm as possible, by putting the muscles upon the stretch.

Mode of percussing.—With regard to the mode of percussing, you should never strike the patient with much force, for by that means you give pain, and do not elicit a good sound. The object is to percuss smartly and quickly; the fingers should remain on the chest but an instant. To percuss effectually, the four fingers of the right hand must be employed; their extremities should be brought into the same line, the index being supported by the thumb. When you percuss a rib, strike parallel to it; for if you percuss it transversely, your fingers will then come upon the intercostal spaces above and below it. Always be careful, too, to percuss also at

the same angle, and with the same force, in comparing the opposite sides of the chest, as a slight difference will occasion a difference in sound, which would not occur if the percussion were properly effected.

It oftentimes happens that the parietes are flaccid, or fat, or the skin of the patient is so exceedingly irritable and tender, that he cannot bear the blow of the fingers, however slight. These difficulties are obviated by the instrument [shewing it] invented by Piorry, called the plessimeter, being, as you see, a round piece of ivory of about one inch and a half diameter, and two or three lines thick. This may be placed on the chest, and a good sound may be obtained by striking it with the fingers, without occasioning any inconvenience. I often place the fingers of the left hand firmly upon the chest, and percuss them with those of the right. Laennec frequently struck the back of the patient by a slight but quick blow with the stethoscope.

Variations in sound at different ages, and in different temperaments.—A very important question arises here, viz. whether the sound elicited from the chest is the same at all periods of life? Certainly not. The sound produced from the chest of a child is infinitely louder than that of an individual in the middle period of life; and that of the latter is also much louder than from an old person. The reason of this we shall inquire into hereafter.

Are there any differences with regard to sex? As a general rule, a louder sound may be obtained by percussing the female than the male chest. The sound is more distinct also in persons of a nervous or irritable temperament, than in those of an opposite character, although of the same age. These circumstances lead to this conclusion, that you should never compare the sounds produced from the chests of two or more individuals, to arrive at a diagnosis, since these persons may differ naturally; but you should compare the different parts of the chest of the same individual.

Variations according to situation.—It then becomes a matter of importance to determine whether the different parts of the chest of the same individual produce the same sounds; they do not. Laennec, to facilitate the study of this subject, has divided the surface of the chest into the following regions.

Regions of the chest.—The *clavicular* region comprises the length of the clavicle: this region is subdivided into the sternal, middle, and humeral portions. The *anterior superior* region extends from the first to the fourth rib; the *superior mammary* from the fourth to the eighth; the *sub-mammary* from the eighth to the twelfth.

That part of the chest which is occu-

pied by the sternum is called the *sternal* region; it is subdivided into the *superior*, *middle*, and *inferior*.

At the lateral parts of the thorax we have three regions: the *axillary* from the highest point of the axilla to the fourth rib; the *superior lateral* from the fourth to the eighth; then the *inferior lateral*, from the eighth to the twelfth.

The posterior parietes have the following regions: the *supra* and *infra spinal*, corresponding to the supra and infra spinal fossae of the scapula; the *interscapular*, between the bases of the scapula and the vertebral column; and the *dorsal*, extending from the angle of the scapula to the last rib.

Nature of sound elicited in the various regions.—The sounds elicited by percussion vary exceedingly in the different regions. Thus the sternal extremity of the clavicle gives a loud sound, the middle less, the humeral portion the least; the sound diminishing in proportion as the space becomes greater between the clavicle and the thorax.

The sternum varies in sound according to the region percussed; thus the superior yields the loudest, the middle somewhat less, the inferior the least,—the latter in consequence of the heart being placed beneath it.

The anterior superior region is very sonorous; the mammary nearly equally so in the male; in the female the sound is dull, from the presence of the mamma. The sub-mammary is dull also on the right side, from the liver being placed beneath it; it is often very loud on the left, from the occasional presence of gases in the stomach.

The axillary and the superior lateral regions sound well; but the inferior lateral does not on the right, from the presence of the liver; and on the left it is frequently too sonorous, from flatus in the stomach.

The supra and infra spinal, and the interscapular regions give fleshy sounds; but the spine of the scapula, and the spinous processes of the dorsal vertebrae, yield them louder.

The greater part of the dorsal region is very sonorous; but the lower portion is dull on the left side, and often very loud on the right, for the reasons I have assigned in speaking of the inferior lateral and sub-mammary regions.

[The lecturer here percussed the chest of one of the pupils, and pointed out the differences between the hollow sounds of the chest and the fleshy sounds of other parts of the body; he also clearly demonstrated the differences of the sounds produced by percussion at the different parts of the chest.]

Inferences arising from the preceding observations.—What inferences are we to draw

from these examinations? First, that any cause which tends to diminish the quantity of atmospheric air in the lung must tend to diminish the intensity of the sound produced by percussion, the sound being dependent upon the presence of air. Thus, when a portion of the lung is consolidated, as in hepatization, the sound given by the parietes of the chest over the diseased part is dull, in consequence of the total absence of air in that part. When a mass of tubercles exists in the lungs, there the sound will also be dull, and for the same reason. Again, when fluid accumulates in the pleuritic cavity, it compresses the lung, and diminishes its volume in proportion to the quantity effused; and in proportion to the diminution of the lung so will the quantity of air be lessened, and the sound elicited from the side affected will be consequently obscure.

Our second inference will be the converse of the last, viz. that any cause which tends to increase the quantity of atmospheric air in the chest must increase the intensity of the sound on percussion. We have two remarkable instances of this; the first in emphysema of the lungs, of which disease I shew you a splendid specimen. Here you see the air cells are dilated; some of them have ruptured and communicated with each other, forming the appearance of blisters upon the surface of the organ; here the quantity of air is beyond the normal proportion; and the part of the chest situated over the portion of the lung affected produced a very loud sound.

The next case is that of pneumo-thorax. From causes which we shall hereafter examine, we occasionally find an accumulation of air in the cavity of the pleura. The chest then sounds like a drum on percussion.

As I have before stated, dyspnoea and cough are signs totally inadequate to the determination of any *specific* lesion of the pulmonary structure, since they are common to them all. By percussion, however, we can discover the locality of the affection, whether it be in one lung or the other, and in what part of the lung; and still more, we can distinguish whether the part be permeable to air or not; but it affords no demonstration of the cause of the impermeability of the organ, as the same dull sound is produced in hepatization or effusion of fluid into the pleura, &c.; nor can we say, when the sound is louder than natural, whether it depends upon emphysema of the lung, or pneumo-thorax. Auscultation overcomes these difficulties.

You thus see, gentlemen, that the method of Avenbrugger affords most important signs of the diseases of the lungs; and it is very probable that Laennec would never have been led to the discovery of

auscultation, had it not been for his previous perfect knowledge of percussion.

It is the fate of all discoveries, however great, to meet with objections; not that I think opposition is of any disadvantage to them, for it forces the discoverer to consider his subject on every side, even if it be only for the purpose of its more complete demonstration; and in doing so, new views often arise, leading him to farther discoveries. Percussion has met with its opponents; but the facts are now too well attested to admit of any doubt; and I recommend your constant practice of it—for it requires it—for the purpose of acquiring an early facility.

SUCCESSION.

We shall defer the subject of Succession, as it applies only to the particular case of pneumo-thorax, with effusion into the pleuritic cavity, until we arrive at the consideration of that disease.

ADDITIONAL OBSERVATIONS

ON THE

VENEREAL DISEASE;

Being an Extract from the Annual Report of Diseases treated in the Hospital of the 72d Regiment, at the Cape of Good Hope, in 1833.

By THOMAS CLARKE, ESQ.

[Communicated by Sir JAMES M'GRIGOR, Bart. with the Author's permission.]

Concluded from p. 41.

THERE is a little more difficulty, and but a little, in respect of the variety of the disease called gonorrhœa. If we find a train of constitutional symptoms following a simple running, analogous to what is so often observed to follow an ulcer on the prepuce, are we not compelled to believe that they are produced by a poison absorbed in the one case, as well as in the other? But we shall be told that the constitutional disease in the former, though simulating the character, is not the same as in the latter; and that it is always milder, and never extending to the second order of parts. Admitting this to be the case, which, perhaps, it is not always, the identity of the poison is not thereby disproved. That gonorrhœa is so seldom followed by constitutional disease, proves nothing. If it is essential to absorption that there should be a breach of continuity, the rarity of constitutional symptoms from gonorrhœa may, in some degree, be accounted for,—an ulcer in the urethra

not being, as far as I am aware, a frequent occurrence. But if any reliance can be placed on the veracity of those I have had under my care, or on my own accuracy of observation, I find a difficulty, with the utmost deference to an eminent authority, of admitting the fact.

I have seen constitutional symptoms make their appearance, during the existence of a running, the primary disease in itself so mild, and so easily cured, that I could not believe in the existence of an ulcer; and I have also seen constitutional symptoms follow a bubo, which had not been preceded by any running or ulcer whatever; therefore, I do not think a breach of surface essential to absorption, and must look elsewhere for an explanation of the fact of the rarity of occurrence of constitutional symptoms from gonorrhœa. And without presuming to give an opinion, I merely throw it out as a suggestion, that perhaps a solution of the problem may be found in the condition or habit of body of the subject. In every such case that has yet come under my observation, the person had been at one time or other the subject of some variety of venereal disease. The experience of the past year enables me to quote two instances occurring within that period.

I have already remarked that no case of primary ulcer, or of ulcer with bubo, admitted into hospital during the past year, has as yet manifested any symptom of constitutional disease: it is somewhat singular that the only instances should have been afforded by gonorrhœa, out of sixteen cases of this variety of the disease, these symptoms having made their appearance in two of them.

A man was admitted with gonorrhœa, rather mild than otherwise. On the fifth day a smart fever came on, with so much constitutional disturbance as to render copious depletion necessary, severe pains in the shoulders and elbows, with a bounding pulse, and great thirst, with dryness and heat of skin. The running had disappeared, and next day the whole body was covered with a papular eruption, and an erythematous inflammation spread itself over the fauces. This state of things continued for some days, and when the eruption began to scale off, the running returned; it soon, however, disappeared again, but the pains in the shoulders and elbows were not entirely removed till after a course

of antimonials and sarsaparilla of three weeks' duration.

This man had been in hospital fourteen months before this time, with an ulcer on the prepuce, elevated, the matter adhering firmly to the surface, with induration. It was healed without the use of mercury, but was tedious, being protracted to a period of thirty-five days.

In the other case the symptoms were less severe, but in character the same. He had also been the subject of previous disease of a gonorrhœa, three,—and of an ulcer on the prepuce, cured without mercury, eighteen months before. It may probably be said that these symptomsought to be attributed to the previous disease; I think that a more legitimate inference would be that the disease was called into action by a fresh poison being absorbed into a previously poisoned habit.

Before taking leave of this subject I must make a few cursory observations on the cases of constitutional disease which have come under treatment during the period embraced by the return.

There were two cases of iritic inflammation accompanied with pains in the larger joints, and copper coloured blotches on the skin.

They had both been the subjects of primary and constitutional disease about twelve months previously, and exposure to cold and wet weather, was the exciting cause in this instance, bringing forward the disease in a new form. In these cases the efficacy of mercury is undoubted and indispensable. The mild tonic action of the Plummer's pill, in conjunction with sarsaparilla, is preferred to all others. The disease yielded gradually, and is to all appearance completely removed.

One very severe case occurred in a recruit, who had lately joined the regiment from Europe. What the primary disease may have been precisely, I do not know, but from his own account I take it to have been phymosis, with one or more ulcers on the internal surface of the prepuce near the frenum. The disease having been contracted in Scotland and very much neglected on the march to the place of embarkation, was aggravated of course, and it became necessary, it would appear, to remove a considerable portion of the prepuce. He was subjected to the influence of mercury before embarkation, and afterwards on board ship, and on arriving

here about five months after contracting the disease, the appearances were, a tubercular eruption over the head, face, and upper extremities, an ulcer on each tonsil, with sharp abrupt edges, the surfaces covered with a thick tenacious yellow matter. Acute pains in the elbows and knees, with inflammation of the periosteum of the tibia, and a scabby eruption upon the scrotum, and general health much impaired. This case required a treatment of three months duration, no mercury was used, and the cure appears to be complete; six months have now elapsed, and no vestige of the disease is visible. The health and strength are perfectly restored.

The next case was one of a papular eruption, generally over the body, of a brownish colour; pains in the elbows and knees, and an erythematous inflammation of the fauces. He had had an ulcer on the prepuce six weeks before, and had been fourteen days in hospital on detachment, and treated with mercury. The cicatrix of the ulcer was gristly and inflamed. After six weeks under treatment he was discharged to duty. On examination three months after, I find the deposition on the prepuce not yet absorbed, and a dryness in the fauces, more particularly in the mornings; therefore I do not consider him safe from a recurrence of the disease, probably in a new and aggravated form.

The next case is that of a man who declares he never had any venereal disease whatever, excepting a running, for which he was fifteen days in hospital in Dublin in the year 1827, and from his character I have no reason to doubt the truth of his statement. He presented himself with an eruption of pustules chiefly on the face; an oblong shaped and ragged edged ulcer on each of the tonsils; pains in the larger joints; with an inflammation of the pericranium, forming a node on the frontal bone. He had been suffering in his health for some time, but it was not until the eruption made its appearance that he took shelter in hospital.

This proved a tedious and intractable cure. The pustules extended themselves over the whole body, in many places running into one another, and forming extensive ulcerations.

The progress of the ulcers in the throat was arrested, but it appeared that the eruption must run its course. A serious impression was made on the general

health in the course of the disease; the debility was considerable. The constitution of this young man being naturally good, I was not unwilling to try its strength against that of the disease. By a steady perseverance in the use of such remedies as are usually employed, excluding mercury, with a diet the least stimulating and most nutritive, and taking advantage of such exercise as circumstances admit of, the disease was made to yield, or exhaust itself. Four months elapsed, however, before he was in a condition to leave the hospital. Since that time, now nearly five months ago, he has enjoyed perfect health in the discharge of his duty.

How this poison, if it was one, was absorbed into the system, relying upon the man's accuracy, may be difficult to explain, admitting it to be a law of nature that absorption does not take place from sound surfaces; but as we have daily opportunities of observing that a secreting surface is capable of being irritated and inflamed, and thereby excited to undue action, is it very unphilosophical to suppose, that the absorbents may in like manner be so excited, and absorption take place from this inflamed surface without an actual breach of continuity? A case of phymosis once came under my care in which the matter had been pent up for several days; on retracting the prepuce, its internal surface, and that of the glans, were inflamed and continued to secrete until the inflammation was subdued, but not the smallest appearance of ulceration could be detected. This was however followed by constitutional symptoms; an eruption, pains, and sore throat. I know with certainty that this was the first venereal disease the person had ever been affected with. This state of things in a less degree might well escape the observation of a soldier, or justify him in saying that he never had venereal.

Whether mercury would have been beneficial or ought to have been administered in the cases above related, is a question into the merits of which I do not at present mean to enter. The last case to which I shall advert, (the remaining cases being slight recurrences of former affections) is that of a man who embarked with the regiment in July 1828, having at the time an ulcer on the external surface of the prepuce. From his own account it would appear that the ulcer was at first disposed to heal,

but afterwards became very painful and spread largely over the surface. He was subjected to mercury and kept fully under its influence, for a period of six weeks, from the effects of which he had not recovered when he disembarked.

Two years and four months afterwards, he presented himself at the hospital, with a few copper-coloured blotches on the shoulders, and complaining of acute nocturnal pains in the joints. These pains proved exceedingly obstinate, leaving and returning to the several joints in succession. After a treatment of upwards of two months, in which mercury was not employed, he was discharged, free from complaint, and continued to do his duty till last winter, during which he came three times to hospital complaining of pains, which were easily removed in the course of fifteen to twenty days. Six weeks ago he presented himself in a very different condition. Acute pains in the joints; a pustular eruption on the head and face; a copious secretion from the membrane of the nose; a node on the frontal bone; and two deeply excavated ulcers on the tonsils. This is the most severe case that has yet occurred; but as it is still under treatment, I must forbear making any remarks until a future occasion.

After what I have stated, I come to the following conclusions:—

1st. That the poison which produces all the varied appearances of venereal sores and gonorrhœa, is one and the same.

2nd. That the matter of gonorrhœa is the parent stock from whence the numerous family of venereal diseases has sprung.

3rd. That the diversity of character of these diseases is determined by many and various circumstances; such as climate, races of men, temperament of body, habits of life, and other influences, some known, and others unknown.

4th. That mercury is not indispensably necessary to the cure of this disease; but as it may be beneficial in some and prejudicial in others, its employment must be left to the judgment and discretion of the practitioner.

Cape of Good Hope,
Dec. 21, 1833.

ON THE NERVOUS CIRCLE OF SIR CHARLES BELL.

By D. BADHAM, M.D.

Fellow of the Royal College of Physicians of
London, &c.

THE nervous circle of Sir Charles Bell has always appeared to me the least satisfactory application of those results of his industry, patience, and talent, which now assist us in explaining the different functions and attributes of the nerves. I will venture to say without reserve, that I consider this eminent physiologist to have completely failed in his endeavour to prove a circle of communication, whether by means of a circulating fluid or otherwise, between the motor nerves of a part, and the nerves of sensation of the same part; nor shall I stop at the still bolder assertion, that I am greatly deceived if the very experiments adduced in proof of this doctrine, might not be used with equal plausibility on the other side. His beautiful experiments, as well on the thirty-one pairs of spinal nerves (in which he so clearly demonstrates the propriety of the anatomical distinction which he has adopted), as on the trigemini (where the analogy with these last is proved to be perfect), leave us nothing to desire, except that he had left matters here, and had not been led into precipitate conclusions from facts so well authenticated.

The fifth pair, as your readers are aware, is a nerve of sensation and of motion, not (as I find myself anticipated in observing by Mr. Walker, in his paper on this nerve lately published in the *Gazette*) as respects one branch, the inferior maxillary, namely, but also as regards the ophthalmic and superior maxillary, which are therefore improperly set down by Dr. Henry as nerves of sensation merely. Being similar in all respects to the spinal nerves, it must, like them, have a compound function to execute. The seventh, on the other hand, is merely a nerve of motion. "How happy, then, are we," says Sir C. Bell, "in the opportunity arising from their peculiarity of course," which is dissociated and different, "of making experiments upon these two nerves, and of ascertaining separately the respective functions of each, without leaving so

much as a pretext for cavil." On these nerves, accordingly, a set of experiments were made, from which the existence of a "circle of nervous communication" was supposed to be established. "We have seen two nerves (the nerves in question) going to the same muscle, divided (unconnected); and when we touched one of these nerves at its extremity connected with the muscle, the muscle was excited; but when we touched the extremity connected with the brain, it was attended with no result. On the other hand, taking the other nerve, also connected with the muscle (branches of which can be seen dispersing themselves to its minutest fibres), and irritating it, as we had done with the former, the muscle was quiescent—no power was propagated in that direction; but taking the other extremity of this divided nerve (connected with the brain) and pinching it, there was pain." Hence he arrives at the precipitate conclusion, that the nervous influence, whether a fluid, a vibration, or some galvanic influence, "cannot be propagated by the same tube backwards and forwards, and in opposite directions, at the same instant of time; but as both nerves are connected with the same brain, and with the same muscle, he infers that the only difference is in the direction in which they convey their impression;" in other words, that nerves of sensation and nerves of motion have different functions, simply from the course of the fluid through them, or the direction in which the impression is propagated.

Such an inference, however, seems to rest upon very insufficient data, and is certainly not warranted from the experiments. In the first place, in touching the muscular extremities of the motive nerve (*portio dura*), how could motion be produced by any other means than the backward current, so to speak of nervous influence from the brain? and if it be here proposed to us how, this explanation being correct, a backward influence did not extend to the muscle when the cerebral extremity of the nerve was excited, it will be sufficient to remind the reader, that the influence in this latter case would not be backward, but direct; so that had we no explanation to offer for this phenomenon of the passive condition of the muscle, it could go no way in assisting Sir Charles Bell's assertion concerning the

inaptitude of nervous influence to travel along the same nerve two ways. But do we not give an explanation of why the muscle was passive in this case, in making the simple statement that the muscle was under the control of the will; but the will was not under the control of Sir Charles Bell's tweezers? Or is the other half of the experiment more satisfactory? This consisted in touching the muscular extremity of a nerve (which his own experiments had taught him to be a nerve of sensation), when no result ensued. Yet had the "nervous circle" contended for by this distinguished physiologist existed, the impression must have travelled to the brain, must have slid down the nerve of motion, and must have caused the muscle immediately to contract. How, if we admit the supposition of Sir C. Bell, are we to account for the absence of all motion here, unless, indeed, we could shew that the motor nerves were all paralysed, and incapable of transmitting the impression? Lastly, when we are told that by pinching this same nerve of sensation at its cerebral origin pain was felt, it is not out of place to remark, that pain, in the first place, is not an attribute of nerve but of brain*;

* In a paper recently published in the Medical Gazette, in examining the evidence upon which certain of the inferior grades of animals are supposed to *feel*, I took occasion to insist upon the *cerebral seat of pain*. I shall not occupy your columns with a reiteration of the arguments there adduced in support of my views, but cannot forbear alluding again to a speculation which even the most eminent physiologists have countenanced, especially as it has in some instances conducted to as curious a process of reasoning as is to be found in the archives of Physiology. Thus we find Sir C. Bell stating that "there are innumerable animals which have neither brain nor nerves, and yet have life, and sensibility, and motion; but as *these* phenomena can only be ascribed to such an organization, he infers that the *matter of nerve exists*, but is merely *diffused* in their bodies, whereas it is *connected* and bound into fasciculi for connecting different parts and organs in our own." Here we naturally inquire—1, How, if nervous fasciculi are requisite to connect parts in action, there should be a *propagated* action in animals who *have no such nervous fasciculi*, but in which the nervous matter is feigned to be diffused? 2, What evidence have we of sensibility—not organic sensibility, but a power of *feeling pain*—even where we *can demonstrate* a nervous system? 3, unless there be a brain or vicegerent for a brain? If not, if there be nothing in nerve which, as such, intuitively confers sensation? When we see an animal shrink *under* injury, are we to say, with Sir Charles Bell, that it shrinks *from* injury?—the first we see, and expect, from the irritability of its organization; the second is *inferred* from analogy. But what proves the correctness of the analogy? Nay, so far is analogy from assisting

(for pain implies sensation, and sensation is a cerebral function); and, secondly, that in whatever part of the brain pain may originate, it is still invariably referred to the extremity of the

us to this conclusion, it is plainly inimical to it; for the spinal cord and nerves are unlike the brain, cerebellum, and medulla oblongata, in having no spontaneity of action, being *conductors* of motive impulses *from*, and of sensitive impressions *to*, these parts. It has been recently objected, I see, by an anonymous correspondent, to Dr. Henry's statement of their being *mere conductors*, that they are, moreover, plainly subservient to the functions and structure of the vital organs, since these become deranged by extensive disease of the spinal cord, but remain unimpaired by destruction or disunion of the brain, cerebellum, or medulla oblongata." But this, which is true, does not in the least invalidate the position as to the *cerebral seat of pain*, since the functions in question are not subjects of *sensation*, being, in fact, carried on without our cognizance. Again, "all nerves have not the same powers, since a man may be insensible and motionless, and yet *breathe*." The observation is Sir C. Bell's. But if all nerves have not the same powers or office, as the case in point shews, then have we no evidence that the nerves of certain of the lower animals have a capacity for feeling; not even though we see these same animals endowed with motion, for the one endowment depending upon a different set of nerves, by no means establishes the other. Concerning the competency of ganglia to perform the offices of the brain, I have already expressed my opinion; nor should I again have recurred to it, but that I find Sir Charles Bell stating, as reported in the *Lancet*, that if we divide the body of the earth-worm, the *posterior* portion remains writhing and twisting, there being no associated action between its parts; while the *anterior* segment, "labouring under the impression of *pain* in its posterior part, will move away and escape"—inferring, from this experiment, that the *anterior* ganglion in the inferior animals, though small, has *superior* powers over the rest, and is, in fact, a small brain.

The following experiments, often repeated, and always with the same results, shew how my experience is at variance with that of the distinguished physiologist just quoted:—

I took many earth worms: I divided them into two or more segments, at the head, tail, or across the middle of the body; and these were the results obtained:—

1. The caudal segment of the worm twists and writhes *only* when the point of division has been considerably below the anterior ganglion; in fact, when it has occurred near the middle of the body.

2. Such twisting and writhing is temporary; and when it ceases, the motion of *each* segment becomes *progressive, associated, and similar*.

3. In other cases, where the division has been effected not very far from the head, the progressive associated action of the links occurs from the very moment of separation.

4. If the number of segments be greater than two, the same results occur.

5. If the worm be cut in two near the head, the head dies, notwithstanding the presence of the "superior anterior" ganglion, long *before* the caudal segment of the same worm, or before any other larger segments of worms, which may have been operated upon at the same time.

Cor. Hence this anterior ganglion is not the *officina* of sensation and motion to the rest of the body beyond the other ganglia; for if it were, it ought, as the depot of sensation and motion, to *outlive* the rest of the body; in place of which it is the *first to die*. The same is also proved by poisoning this end with some acrid substance,

nerve. In the case in question, the highly sensitive origin of the injured nerve permitted a sense of pain to be felt at its other extremity; but if there had been a "circle of communication," as there clearly was not, the muscles must have been excited to move by the returning influence along their motor nerves.

The objections to a supposed "circle of communication" between motor nerves and nerves of feeling, made on the fifth and seventh pairs, apply, of course, equally to the thirty-one pairs of spinal nerves. But, apart from the inadequacy of all such experiments to prove the point, is there not something very difficult to conceive, of a nervous influence travelling from the brain on its errand to a distant organ along its motive nerve, causing that organ to move, and then whisking up again by its associate nerve of sense, bestowing feeling, back again to the brain? or, that a drop of the same identical nervous fluid should touch one nerve's feelings and excite another nerve's motions?

Sentient and motive nerves are no doubt very intimately connected. Sir

when the remainder of the body is found not to be less active or alive.

6. If a worm be divided into two *equal* segments, the caudal segment outlives the other.

Cor. There is, therefore, *more* vitality in the posterior half of a worm than in the anterior segment. Thus, in an eel or serpent, a blow on the *tail* goes further towards paralyzing the animal than any mutilation of the head or anterior part of its body.

In other experiments, where I touched different parts of the body with solid citric acid, which instantly throws the worm into violent convulsions, and destroys vitality in a few seconds, I found that death, commencing in a part affected with the poison, gradually creeps along the body *whichever* extremity be first touched; but that death proceeds more rapidly towards the head than towards the tail, if the middle of the worm be subjected to the action of the poison.

Cor. Which fact, as also the continuity of vascular communication throughout the body apparent to the eye, seems to prove the identity and unity of the worm, and that he is not many, but one.

I may here mention, that on touching the animal's skin with the acid it becomes immediately strongly *corrugated* and *slimy* at the same time; that the animal writhes, and is convulsed. This circumstance by some would be quoted as an evidence of *soreness* or *pain* felt by the skin; but I would remind such objectors of Professor Weber's experiments on the sensibility of the skin, in which he shows that those portions of it sensible to the influence of *touch*, and in this respect alone the most sensitive, are by no means the same parts that are capable of the highest degree of *pain*. The sensibility to *touch*, and the sensibility to *pain*, were found frequently to bear an *inverse ratio* to each other. The first might be called the *irritability* of the skin, and must depend upon a different nervous influence from the one we are considering.

Charles Bell has shewn this; but they are not connected in this way. Indeed all idea of such a circle being necessary must be given up, if we reflect upon cases where there is a paralysis of motion, but not of power, and *vice versâ*; because in such cases the influence which communicates motion or sense from the brain can only (by the very supposition) travel in a forward and backward course, or the reverse. Sir Charles Bell had seen several patients "who had paralysis of sensation upon one side of the tongue and mouth, without loss of the muscular action;" and here, he observes, we are taught how necessary sensation is for regulating motion; since, in all those persons, food was suffered, unconsciously to themselves, to lie between the gums and cheeks, and even to putrify there." But why not attribute this accumulation of food, I would ask, to the loss of sensation of the muscle to external stimuli; by which, as in ordinary cases, and through the medium of the nerves of sensation, the mind would have been instructed where the food lay, and have effected its removal by a proper control over the voluntary muscles?—an explanation quite as adequate as that of supposing the error to originate in the mind's not being able to comprehend the state of the muscular action, and so of controlling it properly. Suppose, for an instant, the mind conscious of the motion of the lips and mouth; yet could it never direct them to remove what, from a paralysis of sensation, they could never feel. In this way, too, the occurrence of inflammation in permanent insensibility of the eye-lid, is, I conceive, to be accounted for. It is impossible to deny that "muscular motion is governed by means of consciousness or perception of that motion, without which we could not balance our bodies in walking, &c.;" but I by no means admit the inference, "that it can only be from a sense of the condition of the muscles of the hand and arm that one knows their position when they do not touch any thing, and when, therefore, the sense of touch does not guide to the conclusion." Surely it must be by the sense of touch that this perception of the condition of the muscular action is obtained—that is, by pressure upon the nerves of sensation, consequent upon the very act of motion. But to return from what is irrelevant: this circle of nervous communication

appears to be directly disproved in all those instances where there occurs a paralysis of sensation without a corresponding paralysis of motion, and *vice versâ*; and on the other hand, I can conceive of no instances which favour such a supposition. To adopt, for example, a case by way of illustration, from Sir C. Bell. In the act of groping for a piece of money, the steps will be as follows:—1st, the will puts the voluntary muscles into motion; then, 2dly, their play makes them press upon the sentient nerves; which, 3dly, transmit this new impression to the brain; which, lastly, coins it into a sensation. Here it appears that it is not the same influence that first moves the muscles, and afterwards returns along the nerves of sense, to inform the brain how it had performed its mission; so that there appears, in fact, nothing to countenance Sir C. Bell's affirmation, that there is but one influence, motive or sensitive, according to the direction in which it is transmitted; an opinion, by the way, expressed long ago, by Petit, the learned commentator on Aræteus, who refers us to a certain book: "*De motu animalium spontaneo in quo,*" says he, "*vim movendi et sentiendi unam naturam eandemque esse demonstravimus.*"

Sounds of the Heart.

P.S.—The nature of the sounds of the heart has occupied, and is still occupying, no inconsiderable portion of the attention of the physiologist. Perhaps the obscurity in which the cause of these sounds is involved, may in some degree be removed by the following experiment. If the *venæ cavæ* be suddenly tied near the heart, in an animal just struck down, while this viscus is yet beating, it is then that it will speedily come to emulge its cavities, while the ingress of fresh supplies of blood from behind is effectually prevented; and by applying the cylinder in this exsanguine state of the organ, it will be easy to determine to what extent, if to any, the sounds of cardiac action depend upon the motion of the blood through the cavities, or to the reaction of the valves upon this fluid; and also how much, if at all, the contraction of the muscular fibre aids in their production.

OBSERVATIONS

ON

MR. STAFFORD'S CASES OF STRICTURES OF THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

HAVING lately read Mr. Stafford's cases, in the *Medical Gazette* for 14th of June and 5th July last, I was particularly struck by the unqualified and unequivocal manner in which he states the safety with which his perforator for strictures may be used.

My own impression of the instrument, when first I saw it, was, that it was a very unsafe one, and could not be used at any part of the urethra without great hazard of wounding the sides, but more especially at the curve; and we know that a very slight division of the internal membrane is enough to be followed by great mischief, if the urine infiltrates through it.

At page 381, June 14th, Mr. Stafford positively asserts "that the operation of perforation of stricture had never been attended with the slightest injury;" and at page 479, July 5th, he says, "In conclusion of these remarks, I beg again to repeat that I have never known any mischief arise from the operation: the pain has been trifling—not more, nor even in some cases so much as the puncture made in bleeding. There has never been hæmorrhage from the cutting; no false passage made, no extravasation of urine, nor abscesses formed in consequence; nor, indeed, has there been, in any instance, a single unfavourable symptom occur. The treatment has always been attended with success, and the patients, from having been in a state of disease, being emaciated and worn out by their long sufferings, have in a short period been so relieved that they have gained flesh, and have become healthy and strong."

Now, sir, such an assertion, accompanied by the selected cases published in the *Gazette* for July 5, would lead many practitioners to consider this as a most safe and easy way of curing a complaint which, when it produces retention of urine, has always been considered as a very formidable one by the most experienced surgeons, and might induce many

young surgeons to undertake an operation that would often disappoint them in the result, and be the cause of their patient's death. As a proof that such a result of the practice might follow, I have sent you the following case for insertion; which, at this distance of time, I should not have thought of publishing under any other circumstances, but that I think the medical public ought to be in possession of the unfavourable as well as the favourable side of the question.—I am, sir,

Your obedient servant,

M. W. ANDREWS.

Arlington-Street, Oct. 9, 1834.

CASE.—J. A., an army surgeon, had suffered from the effects of strictures in the urethra upwards of thirty years, the last seventeen of which he passed in India, during which time the symptoms increased to a very distressing degree; and he informed me he had, on many occasions, taken long marches with a catgut bougie secured in the urethra, which he could seldom pass further than six inches from the external orifice. He also informed me that he often applied the *argentum nitratum* (himself) to a stricture at $2\frac{3}{4}$; which he found relieved spasm, and generally induced the urine to pass more freely.

Before I saw him, he had been under the care of a very experienced hospital surgeon for upwards of six months; who, he said, had applied the caustic upwards of sixty times, without his having derived any benefit. On the 9th November, 1827, he first consulted me; at which time he was in a state of great general irritation, and could only pass urine by drops, or in a very fine stream, with great straining and pain. He was constantly introducing a small catgut bougie, and was obliged to take frequent doses of opium, to relieve spasm of a most painful nature. This long-continued state of suffering had rendered him very nervous and extremely irritable, amounting sometimes to delirium, and often (he said) made him doubtful of being able to resist the temptation of putting a summary end to his sufferings.

On examining the urethra by a bougie of the size that the orifice would readily admit, I found that it would not pass further than one-fourth of an inch; and on introducing one full three sizes smaller, it was arrested at $2\frac{3}{4}$.

It was to this stricture that he had so

frequently passed bougies armed with lunar caustic, and sometimes with *kali purum*; but never succeeded in getting armed bougies beyond that point, and from the frequent introduction of them had completely blackened the orifice.

I told him it would be in vain to expect any benefit until the first stricture was rendered pervious to a bougie of a size that the orifice would readily admit; to effect which, I applied the *argutum nitratum*, and requested him not to irritate the parts by the introduction of the catgut bougie, which, from being used for two or three times, became rough.

This, however, he had been so long accustomed to do on the slightest irritation, that he could not be persuaded to refrain from it. In addition to the repeated attacks of local irritation, his constitution had suffered considerably, and he had frequent paroxysms of rigors, succeeded by the hot and sweating stages. These occurring frequently during the treatment, caused several delays, and intervals of a week or ten days between the applications; and having, on the 2d December, had a very severe attack of irritation, accompanied by rigor, and constant desire to make water, which only passed by drops, attended with extreme pain, I proposed the puncture of the bladder through the rectum, and thereby establish an artificial outlet for the urine; and, by thus relieving the urethra of one material source of irritation, allow the treatment of the strictures to be persevered in with a greater prospect of success.

Having punctured the bladder under similar circumstances on four different occasions, (one of which was in June of the same year, and published in the *London Medical and Physical Journal* for November*), and all with perfect success, I could with confidence recommend the operation; and after explaining to him my reasons, he readily consented; but whilst I was gone home to get the trochar, a medical friend called on him, who, being informed of my intention, dissuaded him from having it done, and excited great alarm in his mind both as to the immediate effects and future consequences of such an operation, telling him, that if it succeeded in affording him relief, the wound in the bladder would remain open, and he

would be a dribbler through life, and consequently could have no enjoyment in society; and recommended that another opinion should be taken on his case before he submitted to my proposition.

I was, therefore, requested to make an appointment with a gentleman, an hospital-surgeon of great celebrity, which I was most happy to do, and we met at eight o'clock that evening. The result of our conference was, an objection on the part of my colleague to the proposition. It was proposed by him to divide the strictures with an instrument, constructed on the same plan as Mr. Stafford's, only straight instead of curved, as being best adapted to the situation of the stricture; the handle of the instrument was graduated.

The whole treatment of the case was now placed in this gentleman's hands; and on Sunday, 23d December, he divided the stricture nearest the orifice with an instrument of his own invention, which he had often successfully used in cases where the external orifice had become contracted, and the parts were kept from uniting by the frequent introduction of a metallic bougie down to the second stricture: a few drops of blood only followed the division of this stricture. He experienced great relief after this operation, and thus far every thing was very promising.

On Sunday, 30th, having first accurately measured off the distance on the graduated scale, and adjusted the lancet to the extent it was intended to protrude through the canula, the instrument was passed down to the obstruction, and the lancet pushed gently forward two or three times, advancing the canula as the stricture was divided. The pain, however, was so severe, (in consequence of the large size of the canula, which was with difficulty passed down to the stricture), producing large drops of perspiration over his whole body, that it was thought right to withdraw the instrument, and lay the patient on his bed, to prevent actual fainting. Nothing more was done that day; but it was proposed to complete the operation on the following day with an instrument of a smaller size. Very little blood followed; an opiate was given, and he was put to bed.

The pain he experienced at each time the urine passed during the remainder of that day and night was very excruciating; and on the following morning

* *I* vide *London Medical and Physical Journal* for November 1827, p. 397. See also other cases in the 2d edition of my work on Strictures.

there was swelling and an erysipelatous blush over the pubes, with acute pain and great tenderness, which extended down to the perineum; but there was no swelling or pain at the seat of the stricture. Leeches and fomentations were applied, and his bowels freely evacuated, by which means the symptoms were greatly mitigated, but never wholly subdued.

In a few days he had irregular rigors, sickness, and hiccup. The stomach became so irritable as to reject every thing. He became comatose, and on the 11th January, 1828, died at 8 p.m.

Appearances on dissection the following morning.—On laying open the abdomen, dividing the integuments over the pubes, and removing the skin from the penis, the parts presented a complete state of gangrene. The left corpus spongiosum urethrae was in a gangrenous state, and the left crus penis nearly destroyed. Slitting open the urethra, the stricture, at $2\frac{3}{4}$ inches from the orifice, was found to have been nearly divided through its whole extent, which was about three-quarters of an inch; but so small was the opening by which the infiltration of urine had taken place, that it could not be detected; probably the state of the parts contributed to the obscurity of it. There could be no doubt, however, but the whole of the mischief had been produced by that cause.

There was another stricture at the membranous part of the urethra, which was of the usual extent, rather more than a line, and would probably not have formed any impediment to the passing of the catheter, had the other stricture been perforated through its whole extent.

The bladder, as might have been expected, was in a very diseased state, as was also the liver; and the mucous membrane of the stomach was thickened and inflamed, or rather much injected.

REMARKS.—In this case, every evil that could have been apprehended *a priori*, from the use of a cutting instrument in a part like the urethra, where the eye cannot direct, took place; and as the operation was performed by an hospital surgeon whose experience and abilities are unquestionable, and who used the greatest possible precaution, by first measuring off the exact distance

from the external orifice, and setting the lancet so that it should not be protruded further than he thought necessary, the failure cannot be attributed to want of care or unskilfulness of the operator, which, had it been done by a person of less experience and practice, might have been considered to have been the case.

At page 133 of Mr. Stafford's book, this case is given; but the fatal termination is ascribed by the author to other causes. There is no doubt that the subject of this case must have eventually fallen a victim to his complaints (as many others have) if nothing had been done to relieve him; but it appears to be equally indisputable, that the immediate cause of his death was "the operation."

In reading Mr. Stafford's book, it would appear that on many occasions he has been successful in the use of his instrument; but the statement of his cases by no means justifies the unqualified encomiums he passes on it.

Case I. page 93, is one in which leeches had been applied several times previous to the operation, by which we should have expected the patient would have been so well prepared as not to have exhibited inflammatory symptoms after it; notwithstanding which we find that inflammation did follow, requiring a repetition of them twice to the perineum, and once to the groin; and we are informed that the man eventually left the hospital *nearly* cured.

Cases II. and III. pages 99 and 103, also required leeches to subdue inflammatory symptoms after the operation.

Case IX. page 122, is one in which infiltration of urine actually took place; "the symptoms became more alarming; both testicles swollen, and actually painful;" "perineum tense, and acutely painful on pressure," which symptom did not give way till "an incision had been made down to the urethra, and about a table spoonful of pus escaped." Pus and urine continued to be discharged from this opening for several days.

In the case of Sir Herbert Sawyer*, where the post-mortem examination is described by Mr. Stafford, we find "a newly-made canal terminating in a blind extremity, which was about three-quarters of an inch from coming out of the urethra on the other side of the stricture;" and this, as Mr. Stafford says,

"no doubt was produced by the perforation of the lancetted stilette, or urethral perforator."

We have here a complete contradiction (in Mr. Stafford's own words) of the assertions he has made. How he can reconcile this discrepancy, I must leave for him to explain.

CASE OF APOPLEXY, WITH DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

SHOULD YOU consider the following case of apoplexy, with delirium tremens, of sufficient interest for insertion in your valuable publication, it is much at your service.—I am, sir,

Your obedient servant,
WILLIAM ROBBS.

South Terrace, Grantham,
Oct. 7, 1834.

Mr. R., aged 36, of middle stature, inclined to be corpulent, with rather a large head and short neck, has been for years in the habit of drinking large quantities of spirituous liquors, generally a bottle of brandy a day, besides wine; and some days much more. Has several times been afflicted with disease. For this last year he has not taken his accustomed exercise, but led a very sedentary life, still continuing to take large quantities of animal food, and indulge in his usual dram-drinking. He has been rather deaf for some years; latterly his deafness increased, and his memory at times appeared to fail him; he has also been more irritable in his temper. A few days previous to the attack of the following disease, he had changed his liquor from brandy to gin; and the latter always, when in health, affected him more than the former. On the 24th of September he was much intoxicated from both liquors; the exact quantity he drank is not known. On the 25th, the day of the attack, he complained of a violent pain of the head, and took but little food, and not more than half his usual quantity of brandy. About 8 o'clock p.m., whilst asleep on the couch, he suddenly fell down in a fit of apoplexy, was quite insensible, breathing with difficulty, at the same time blowing with violence a viscid mucus, tinged with blood, from the

mouth and nose; the pupils of both eyes were fully dilated, and did not contract on the approach of a strong light; the pulse was slow, oppressed, and beating about 84 in the minute; the action of the heart was performed with great labour; the temperature of the skin, except about the head, was below the natural heat, with profuse perspiration. He was seen immediately on the attack by a medical friend, Mr. C. Arnold, who, on my arrival, was proceeding to bleed him. About thirty ounces of blood were taken from a large orifice from the median vein of the arm before sensation returned, or the stertorous breathing was relieved. From this sudden abstraction of blood the pulse became more expanded, beating 120 times in the minute. After a short time he became conscious, recognized his friends, and with assistance was able to walk to bed. He expressed himself relieved, but complained of violent pain about the back part of the head; he attempted to utter many words which he was unable to do, from partial paralysis of the muscles of the larynx.

R Hydr. Submur. gr. v. 2da quaque hora sumendum.

R Magnes. Sulph. ʒ. ij.; Ol. Crotonis, mss. (solve ex Spt. Rect.); Tr. Sennæ, f. ʒij.; Mist. Camph. f. ʒix. Fiat haust. 3tia quaque hora sumendus. Applicetur Empl. Lyttæ nuchæ.

10 o'clock p.m.—Was called hastily, in consequence of a relapse into another fit similar to the last. Both pupils were more contracted; the pulse became slower, and the action of the heart appeared to be performed with great difficulty.

Repet. detractio sanguinis ad f. ʒx. Sinapisms to be applied to the pit of the stomach and to the lower limbs.

Shortly after the last blood was taken away, and as soon as the sinapisms began to act, he again became conscious, and appeared relieved. I then left him, giving the attendants directions to continue his medicines.

Sept. 26th, half-past 1 o'clock a.m.—He again relapsed into his former state; the pulse was about 130 in the minute; the carotids and temporal arteries were beating violently; the pupils of both eyes were much more contracted and insensible to light. The friends of the patient becoming greatly alarmed, and the symptoms appearing very slightly relieved, I requested the assistance of

my friend, Dr. Turner, who promptly attended; and it was agreed, in consultation, that ten ounces more blood should be withdrawn, the patient's head shaved, an evaporating lotion constantly applied, and to persist in the remedies already prescribed.

5 o'clock A.M.—Dr. Turner and myself met in consultation. We found the patient awake; he recognized us, and was conscious of what was going on in the room. The bowels had been freely relieved of dark evacuations; the pulse was about 140 in the minute.

Pergat.

10 o'clock A.M.—The patient had been asleep; he appeared now quite sensible. He complained of griping pains of the abdomen. There was still hesitation in his pronouncing certain words. No pain of the head, but considerable uneasiness about the liver and spleen. The tongue was moist and rather white; the pulse 120, full and soft.

Cont. Pulv. 4ta quaque hora cum haustu sequente.

R Dec. Aloes Comp. f. ʒj.; Vini Colch. f. ʒss.; Mist. Camph. f. ʒss. fiat haust.

7 o'clock P.M.—He appeared better, and had no relapse during the day.

Pergat.

27th, 10 o'clock A.M.—Had passed a comfortable night; there was slight pytalism; bowels freely open; he complained of no pain save of the mouth and teeth; great thirst; tongue moist and rather white; pulse 100 in the minute, and soft.

Ordered to discontinue his powders.

Continue the draught.

R Sodæ Sub-boratis, ʒiv.; Mellis, ʒss.; Aquæ Distil. f. ʒv. fiat gargarismus, sæpe utendus.

6 o'clock P.M.—He appeared going on well in every respect.

28th, half-past 10 o'clock A.M.—Complained during the night of slight illusive visions, and was unable to get to sleep before dawn; after that he slept well between three and four hours. After he awoke he was perfectly collected, said he felt refreshed, and with the exception of his sore mouth suffered no pain. During yesterday he could not be prevailed on to take the quantity of brandy prescribed; the tongue was moist and clean; the pulse 110, and feeble.

Ordered to take an increased quantity of spirit, and beef-tea strongly spiced.
R Spt. Ammon. Arom. ʒxl.; Decoct. Aloes Comp. f. ʒij.; Mist. Camph. f. ʒix. fiat haust. 3tia quaque hora sumend.

R Hydr. c. Creta, gr. vj. vespere sumenda cum haustu sequente.

R Solut. Morph. Mur. ʒxl.; Aquæ Distil. f. ʒj. fiat haustus.

8 o'clock P.M.—I was summoned hastily to meet Dr. Turner, in consequence of the patient declaring he was dying. On our arrival we found him sitting up on the bed, with an expression of great anxiety. The skin was cooler than natural, covered with a profuse perspiration, and the tongue moist, covered with a white fur. Pulse 100, and feeble. He complained of no bodily pain, but said he felt certain he was dying.

Ordered to take brandy and sago frequently.

R Pulv. Opii, gr. v.; Hydr. Subm. gr. iij. ft. pil. st. s.

R Pulv. Opii, gr. j.; Gum. Camph. gr. iij. fiat pil. 3tia hora cum haustu sequente, sumat.

R Amm. Carb. gr. v.; Tr. Valerianæ, f. ʒj.; Aq. Menth. P. f. ʒj. fiat haustus.

Half-past 10 o'clock P.M.—The patient presented all the symptoms of delirium tremens in a more decided manner. There was continued agitation of the extremities and whole body; the ravings were incessant, and very violent. When we attracted his attention he was able to recognize us, but immediately relapsed on the same subject. The skin was cool, and covered with a profuse perspiration.

Ordered to take a pill every hour, alternately with brandy and water and the draughts; and to have the following liniment rubbed over the pit of the stomach:—R Linim. Amm. ʒj.; Morphicæ Mur. gr. iij. ft. Linim.

29th, half-past 3 P.M.—The delirium continued with the same degree of violence; he had taken twelve grains of opium without the slightest effect; the pulse was more feeble, and the tongue and mouth more dry, loaded with viscid mucus.

Ordered to continue his brandy, and to take Tr. Opii, ʒxx. 2da hora.

9 o'clock A.M.—Still continued in the same delirious state; pulse more feeble, and increased in frequency; tongue more dry and becoming very brown.

There appeared to be a disposition to sleep.

R Tr. Opii, ℥xx.; Tr. Valerianæ Am. f. ʒj.; Mist. Camph. f. ʒix. fiat haust. 2da hora capiat.

Noon.—He was in a disturbed sleep, having great difficulty in breathing, with a mucous rattle in the trachea, and constantly moaning.

5 o'clock, p.m.—He had awoke, and, after much exertion, expectorated some viscid mucus. He took a small quantity of brandy, with water, and again fell into a comatose state. The breathing was performed with great difficulty, and the mucous rattle continued. The pulse was very feeble, and appeared to be a continued stream.

9 o'clock, p.m.—Had been gradually getting worse since our last visit. He appeared conscious, but was unable to swallow. From this time he sunk rapidly, and died about midnight. There was no postmortem examination.

Cases similar to the one just related, are, unfortunately, of frequent occurrence in private practice; and I know of no disease more difficult to bring to a happy termination than apoplexy in an individual who is not only a free liver but also a free drinker of spirituous liquors; for in every case of apoplectic seizure, the medical attendant is imperatively called upon to take blood, and not a little, but to continue till some appearance of returning sensation is made visible; and as certain as reaction takes place, almost so certain will the sequel be "delirium tremens."

It will be observed in the preceding case that blood was taken with considerable caution; so much so that venesection was had recourse to three different times, and the amount that was necessary to be extracted before the patient was relieved from immediate danger, was no small quantity. The patient slept heavily after this loss of blood; his breathing continued stertorous, and there appeared no impropriety in these active measures, but the reverse; indeed, the day following, the patient was surprisingly recovered; he complained of no pain, uneasiness, dizziness, or other uncomfortable sensation of the head, but referred his complaints to the abdomen. The night following he passed in comfortable and refreshing sleep. On the second day appearances were favourable, but on this day he refused to

take brandy, and could not be prevailed on to do so. During the night following he had slight visions, and a dread of going to sleep; still, however, after break of day, he slept several hours, and when he awoke he appeared collected and refreshed. It was not till Sunday evening the delirium assumed its true form, and we considered the previous restless night to be owing to the patient's not taking sufficient stimulus during the preceding day; and he was therefore ordered to take an increased quantity. On the Sunday evening there was no doubt about the nature of the existing malady, and however inimical opium may be to an apoplectic patient, it is our only remedy when that patient is suffering from delirium tremens.

It will be observed that about sixty hours elapsed after the abstraction of the last blood, before decided symptoms of delirium came on. I have more frequently found it about twenty-four or thirty-six hours after venesection; but I think it questionable whether the patient, omitting to take any stimulus after being accustomed to large quantities, might not be as great an exciting cause of the delirium as the abstraction of blood itself.

It is very manifest, from the history of this patient's life, that his constitution was completely broken up from hard drinking; and that, when once attacked with a violent disease, there would not be a chance for his recovery.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

An Inquiry into the Nature of Sleep and Death; with a View to ascertain the more immediate Causes of Death, and the better Regulation of the Means of obviating them. Republished, by Permission of the President and Council of the Royal Society, from the Philosophical Transactions for 1827-29-31-33, and 34; being the concluding part of the Author's Inquiry into the Laws of the Vital Functions. By A. P. W. PHILIP, M.D. F.R.S.L. & É. &c.

THE Philosophical Transactions are so little in the hands of the members of our profession, that there is ample room for the republication of the papers relating to it. The particular nature of the pub-

lication before us induces us to give an earlier notice of it than we should otherwise probably have done. It is surprising that, in such an age as the present, physiology, although (as the author observes in his Introduction) forming, with anatomy, the basis on which the science of medicine rests, should be so little cultivated by the members of our profession. It is rare, even in the medical journals of this country, to see a correct account of a physiological work, which includes any thing beyond the more superficial parts of the science; and we often find the reviewer giving the most decided opinions, which only shew how ill entitled he is to give any opinion at all on the subject.

Our limits will not admit of our giving an analysis of all the papers republished in this volume. It is several years since the first five papers appeared; one of the most important of which—that on the powers of circulation—we republished at the time of its appearance. These essays, however, were only preparatory to the two last papers, which form the chief subject of the publication—those on the nature of sleep and death. Of the former of these we put our readers in possession, as well as expressed our opinion of it, by republishing it at the time it appeared in the *Philosophical Transactions*. The paper on death is too long for republication, but we shall here give such quotations from it as will, with the intervening observations, make the reader acquainted with its general contents, and also with the leading features of the preceding papers, on which it is in a great degree founded, as far as they are necessary for understanding what we shall say of this paper. We shall begin by quoting the author's account of the general principles on which his theory is based, and his recapitulation of the different forms of death.

"In the last of the papers above referred to," he remarks, "I had occasion to observe that there is no question relating to the animal economy which involves a more general view of its phenomena than the nature of sleep. The nature of death also includes a general view of the functions of health, for such we shall find are the laws of our frame, that these functions alone necessarily lead to death; but the nature of death is a more complicated question. It includes the various ways in which the functions

are influenced by disease, the effects of which are so numerous that they seem at first view a train of countless phenomena which defy all attempts to refer them to general principles.

"I need not say that many advantages would arise from a correct knowledge of the immediate cause of death, and of the different sources from which the state that constitutes that cause arises. The most important would be, that it would give to the physician a clearer view of the tendencies of disease, and consequently of the indications of cure; but it would not be the least of its advantages, that it would tend to strip a change which all must undergo, of the groundless terrors with which, we have reason to believe, the timid and fanciful have clothed it."

* * * * *

"Such is the natural decay of our frames, but, as I have already had occasion to observe, it is very rare for it to run its course uninterruptedly, particularly in civilized life. It is almost always disturbed by adventitious causes accelerating it, or the decay of particular parts, which, in consequence of the mutual dependence of the various functions, disorders the whole. Although these causes are of infinite variety, the laws of our frame are limited, and therefore many must operate on the same principle. This leads us to believe, that, however varied the causes of disease, it may be possible to reduce their more ultimate effects to a few general heads. The exhaustion of the sensitive system, for example, is of the same nature, whatever be the cause of excitement; and other forms of debility, affecting either the sensitive or vital system, cannot be very various, however various the causes which produce them. We have reason to believe that the endless variety of disease depends more on the peculiar nature and functions of the different organs affected, and the peculiar manner in which different causes affect them, than on any great variety in the states which constitute the more immediate causes of death. However various the effects of disease, there must be but a few points to which they all tend, because the last in the chain of causes which produces what is called death, we shall find, is always the same, and seated in the same parts. On these principles we may hope to reduce the effects of the adventitious causes of

death to a few heads, and thus to obtain such a view of the subject as shall enable us to trace the nature, and consequently the operation, of the causes of our decay in individual instances, and therefore to perceive more clearly the operation of the means which tend to counteract them. In the prosecution of the subject, I shall commence with those causes of disease whose operation most resembles that of the wholesome stimulants of life; and in pursuing, by means of the various experiments which tend to unfold the laws of animal economy, the consequences of these causes, we shall be led to the effects of such as have nothing in common with them."

* * * * *

"We have seen that the forms of death—for, as I have already had occasion to observe, the whole operation of the causes of decay, in strict language, constitutes the act of dying—may be arranged under five heads.

"1. The only natural death, that from old age, where all the powers of life, in consequence of the operation of the agents which excite their organs, gradually decline, and death is only the last sleep, characterized by no peculiarity, in which these powers, partly from their own decay, and partly from the lessened sensibility increasing the difficulty of restoring the sensitive system, become incapable of this office, in consequence of which the individual awakes no more; for it is to be recollected that it is not in the commencement, but in the progress of the last sleep, that what we call death takes place. In its commencement we have seen, the sleeper may always be roused by stronger stimulants than those which preceded it.

"All the other forms of death, it appears from what has been said, may be regarded as more or less violent, some adventitious cause disturbing the natural process. They were divided into two classes; in the one the offending cause makes its impression on the sensitive, in the other, on the vital organs. The former were divided into those cases in which the debility which precedes the total loss of sensibility arises from the excess of the stimulant operation of the offending cause, and those in which it is the direct effect of that cause; the latter into those cases in which the vital powers fail in consequence of their organs being deprived of the stimulants which excite them, and those in which

the offending cause makes its impression on these organs themselves, the power of which, analogous to the operation of the offending cause on the sensitive organs, is destroyed, either by the excess of its stimulant, or its more directly debilitating operation, according to the nature or degree of that cause. Thus are induced,

"2. The death which in its nature most nearly resembles the death of old age—that from excessive exhaustion of the sensitive system, from the operation of stimulants of greater power than this system can bear, notwithstanding the intervals of such imperfect repose as their continued operation admits of, without the supervention of disease; which, not being capable of relief from the continued action of the vital parts of the brain and spinal marrow, by sympathy spreads to them, the affection of each system increasing that of the other, till all the powers of the sensitive system are destroyed.

"3. The death in which disease of the sensitive system arises, not from causes over exciting, but directly debilitating it: the debility they produce being of the same nature with that from excessive excitement, and running the same course as in the second stage of the preceding form.

"4. The death which arises from the privation of the natural stimulants of the organs of life; and lastly,

"5. That which arises from diseased states of those organs, analogous to the states produced in the organs of the sensitive system by the causes which make their impression on them.

"If the foregoing include all the modes of decay, the physiological nature of death, in its various forms, is referable to very simple principles. In the natural decay, the excitability of the organs of both the sensitive and vital systems is gradually impaired by stimulants, which, whether existing within our bodies or making their impression from without, belong to inanimate nature; for it is by the impression of such stimulants alone that the functions of life are maintained. In the different kinds of violent death, with the exception of the death which arises from a failure of the natural stimulants of the vital organs, which is comparatively rare and extremely simple in its nature, we find the excitability of one or both of these systems, or some parts of one or

both of them, capable of influencing all the others, more quickly destroyed by the continued operation of causes, which either stimulate beyond the limits of health, or applied beyond the limits of their stimulant operation, destroy the powers of life, either by directly destroying the powers of the sensitive system or depriving it of those powers by which it is maintained. All these causes, it is evident, tend to the same effect, the extinction of the sensibility, which constitutes death according to the common acceptation of the term, the immediate cause of which, therefore, exists in the sensitive part of the brain and spinal marrow."

In his paper on Sleep, the author adduces facts to prove that the functions of the sensitive and vital systems are regulated by different laws; the latter in no degree partaking of the exhaustion which constitutes sleep, the immediate cause of which, therefore, is confined to the sensitive system.

It appears, from many facts referred to in the paper before us, and in the papers which precede it, that the only dependence of the vital on the sensitive system, is for the change effected in the blood by respiration—the only function, properly termed vital, to which the co-operation of the sensitive system is necessary; and consequently that it is through this function alone that the vital system is influenced in sleep, an opinion, as appears from what is said in the paper on sleep, equally supported by the phenomena of sleep themselves. In proportion as the sensibility is lessened in sleep, respiration (which, in the fifth paper, on the relation which subsists between the nervous and muscular systems, is shewn to be altogether an act of volition) is rendered slower, and, in consequence, the organs of the circulation, and other vital functions which depend on it, are less readily excited. But while health continues, the change is in their excitement alone, their power remaining unimpaired.

By their means, the due excitability of the sensitive system is gradually restored during sleep, again in a short time to be exhausted by the usual stimulants of life.

Thus it is that although the sensitive system is restored by the continuance of the vital functions in sleep, the constant recurrence of its exhaustion at length

enfeebles its powers; and as the interrupted excitement of the sensitive system tends to lessen its excitability, the continued excitement of the vital system, as we might *a priori* expect, has a similar effect with respect to its excitability. Thus, as we advance in life, the sensitive system is less easily restored, and the vital system becomes less capable of restoring it, till at length, the task being beyond the remaining powers of the latter, they fail in the attempt.

Such is the death of old age, which, depending on a gradual decay, necessarily takes place at the time when the functions of the vital system are performed with most difficulty—that is, under the disadvantage of a diminished frequency of respiration, caused by the exhaustion of sleep.

All other modes of death depend on adventitious causes, the more immediate effects of which are infinitely varied, but which, as appears from the results of many experiments, all tend to one change, which constitutes what is called death—namely, the loss of power in those parts of the brain and spinal marrow which are associated with the nerves of the sensitive system; in consequence of which the sensibility, and consequently the respiration, are destroyed.

It also appears from the experiments just referred to, detailed in the author's Inquiry into the Laws of the Vital Functions, that what is called death is but the conclusion of the first stage of the process of dying; for he found that after it, all the vital functions, respiration alone excepted, still continue, but cannot, in the more perfect animals, long survive the loss of sensibility, which is effected in the various ways enumerated in the recapitulation given above; for the illustration of which we must refer to the treatise, where the causes and nature of each are considered at length.

"All modes of death (the author observes), with the exception of the death from old age, may be regarded as more or less violent; but in considering their nature, we must not confound the last act of dying with the suffering which precedes it, and which is often no less when it terminates in recovery than in death, which equally relieves it; and as death, in the usual acceptation of the word, from whatever cause it arises, consists in the loss of the sensorial functions alone, the act of dying is, in this respect,

in all cases essentially the same. In all my experiments I found the nervous and muscular surviving the sensorial functions*.

"When the animal no longer feels and wills, he is what we call dead; but for a certain time the motion of the blood in every part of the system still continues, and all the assimilating functions still go on, as may be demonstrated by dividing the vital nerves immediately after death, which produces the same change of structure in the organs supplied by them, though in a less degree, as during the life of the animal†; and that all this would be the case, a knowledge of the animal economy would have told us, independently of the aid of experiment, if we could, without this aid, have acquired it.

"The removal of the sensorial powers neither destroys the muscular power nor deprives the muscles of involuntary motion of the stimulus which excites them. The heart, indeed, is incapable of its function, because, from the interruption of respiration, its left side is no longer supplied with the kind of blood which is its natural stimulant; and the accumulation of the blood in the lungs, from the same cause, affecting a great proportion of its vessels, prevents the right side from emptying itself. These are the necessary and almost immediate effects of the interruption of respiration; but the change in the blood of all the capillaries, with the exception of those which belong to this class of vessels, necessarily takes place more slowly. A certain time must always elapse before the stoppage of respiration greatly affects it. It has been sent to these vessels more or less in its proper state, and it still finds its vessels capable of being influenced by their usual stimulant‡. Thus, as I have ascertained by many experiments, the motion of the blood continues in these vessels for several hours after respiration has ceased—that is, as long as the blood can be drawn from the larger arteries, the cause of these arteries being found empty after death§.

"But this is not all: the nerves of the ganglionic, as well as cerebral system, retain their power for a certain time after the supply of that power from the brain and spinal marrow has ceased*. The blood, therefore, still finds the secreting surfaces more or less in a state capable of their functions; and the secreting processes, as I ascertained by frequently-repeated experiments, still go on†. Nor is even this all; for the brain and spinal marrow depend, for their functions, on the same powers as other organs; and I found, by an experiment made on so large a scale that it was impossible to be deceived in the result, that there is an actual supply of nervous influence after the sensorial functions have ceased—that is, after what is called death‡."

In considering the various adventitious causes of death, we have seen, the author begins with those, the operation of which most resembles that of the usual stimulants of life; and in pursuing the effects of these, he is led to those which have nothing in their effects in common with those stimulants; for the stimulant operation of agents, if either too powerful or too long continued, produces the same state, which is their more immediate effect when they are applied in such quantities as act as sedatives, any degree of which is inconsistent with the functions of health; the sedative effect being of the same nature, and equally a state of disease, whether arising from the excessive application of stimulants or the more direct effect of the offending cause. All agents capable of influencing the living animal, may act either as stimulants or sedatives, according to the degree in which they are applied. It would appear, from a passage referred to in the author's Inquiry into the Laws of the Vital Functions, that whether the agent makes its impression on the mind or body, there is no exception to this law. Our limits do not permit us to follow the author in the various ways in which the functions are influenced by diseases, and the sympathies which so extensively influence and are influenced by them. Having enumerated them, he proceeds—

"Such, in different cases, is the va-

ried course of our decay previous to the moment at which the sensibility is extinguished, emphatically called that of death, because it completes the decay of the sensorial powers, and leaves us only those which we possess in common with the vegetable world; for the vegetable, like the animal, can convey its juices, from its secreted fluids, and in some instances move its limbs, if proper stimulants be applied; an additional argument, it might be shewn, if any were required, for all such functions being the effects of inanimate agents acting on living parts.

"After the removal of the sensorial functions, none remain to us but such as are maintained by the immediate action of those agents. Our bodies are hastening to be mingled with the matter of inanimate nature. They retain only those powers which immediately depend on its agents, and these are rapidly failing, because, for reasons which have been pointed out at length*, the due application of those agents in the more perfect animals, cannot long survive the loss of the sensorial powers.

"The power of organizing the elements of inanimate nature belongs, and some have supposed exclusively, to the vegetable world; but as we see plants, the mushroom tribe, possessed of no organizing power, and therefore, like animals, nourished only by matter already organized, some of the lower species of animals, on the other hand, seem to possess this power. Thus it would appear that there is a class of animals and of plants in which the animal and vegetable, in this essential respect, exchange their natures. As the animal becomes imperfect, and approaches the nature of the vegetable, the sensorial powers dwindle, and the lowest animals appear to extract their nutriment from air and water, which, being generally diffused, are at hand, and consequently obtained without any sensible effort on the part of the animal. His life, therefore, although not independent of the external world, is, like that of the vegetable, independent of any act of volition. As we rise in the scale of animals, the sensorial powers increase, and, in the same proportion, become more essential to existence. From those animals which obtain food without any act of volition, we come to those who can only obtain it

by such an act, but who still, without any act of this kind, obtain the influence of the air, yet more immediately necessary to their existence. We arrive at length at the most perfect class, which can neither obtain food nor air, except by an act of the sensorium. In them the sensorial power is as necessary for the inhalation of air, as the ingestion of food. When sensation ceases, they as certainly cease to breathe as they cease to eat. Thus it is that in this class of animals the due application of the inanimate agents on which life depends, cannot long survive the loss of the sensorial functions.

"As we have been enabled, by the aid of the experiments referred to in the foregoing paper, to trace the steps by which the sensibility in the various forms of death is extinguished—that is, of our decay up to that moment which has, for very evident reasons, obtained the name of death—by the same means we may with more ease trace the steps by which the remaining powers of life are extinguished.

"As the powers of life fail, we have seen, the first functions which cease are those which wholly depend on these powers. The others, being the results of inanimate agents acting on vital parts, continue as long as those agents are supplied, for the purpose of exciting their organs. The first of these powers which fails is evidently the power of the capillary vessels, because their function continues as long as any blood can be supplied to them from the larger arteries. The circumstance of the action of the capillaries only ceasing when the larger arteries are empty, affords a proof that the assimilating processes, without which their power would fail, are still more or less in a state of activity. These processes, we have seen, are immediately dependent on the vital parts of the brain and spinal marrow. The due mechanism of every part, it appears from direct experiment, depends on the action on the blood of the agent they supply. When the capillaries can no longer supply the blood on which it acts, it is evident that the functions of this agent must cease, and consequently that those parts of the brain and spinal marrow by which it is supplied, being thus deranged, their powers must cease also.

"These are the last of the powers of life which fail, and thus the body of the more perfect animal is left subject to the

* The first paper in this volume from the Philosophical Transactions for 1829; and Experimental Inquiry, Part II. Chap. xi.

laws of inanimate matter. The first functions which cease are those of the sensitive parts of the brain and spinal marrow; the last, those of the vital parts of these organs*."

In the rapid view we have taken of the paper before us, we have been obliged to pass in silence discussions into which, had our limits admitted of it, we should have entered, and to some of which we may probably, in a future number, recur; such as that respecting the state of the body in suspended animation, and the suggestions for improving the modes of treatment in it; the discussion respecting the cause of the growth of the body, and the circumstances which determine its period in each individual; and that respecting the general laws of the animal economy, and particularly the identity of voltaic electricity, and the agent on which depends the secreting and assimilating processes, which the author has for so many years maintained, and in support of which adduced so many experiments; an opinion which gains much additional support from Dr. Faraday's doctrine of electro-chemical equivalents; a doctrine which he so strikingly, and we must add convincingly, illustrates in his papers in the same part of the Philosophical Transactions which contains Dr. Philip's paper on the nature of death, and from which it would appear that all chemical changes are necessarily the effects of electric action.

In an appendix, the author republishes two papers which appeared in this journal, in reply to some strictures in Dr. Prout's Bridgewater Treatise.

* In the first of any of the more perfect animals, unless the nervous influence be supplied from without, the rudiments of the organs which supply it and those of the sanguiferous system must have been simultaneous creations, because neither is capable of producing the other, the functions of each being inseparable from those of the other. But we have seen that it is a necessary inference from direct experiment, that while the vital principle is unimpaired, the powers of circulation, provided the blood be duly exposed to the influence of the air, are, with the aid of voltaic electricity, capable of all the assimilating functions. No other powers are required for the maintenance and growth of the animal body.

We have reason to believe that the vital parts of the brain and spinal marrow may, like the lungs, be inactive in the fetal state, some other means in this state being employed to supply an agent, which after birth can only be supplied by them. Well-grown fetuses, perfect in all their other parts, have been born without either brain or spinal marrow. The growth of such fetuses must depend on the same causes as the growth of other monstrous productions in the uterus—namely, as far as relates to the brain and spinal marrow, on the powers of the mother alone; how applied, it is impossible for us to say.

MEDICAL GAZETTE.

Saturday, Oct. 18, 1834.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL RESPONSIBILITY— CONCLUSION OF THE AFFAIRE THOURET-NOROY.

It is pleasing to observe the *esprit de corps* with which the medical men of Paris have been animated throughout the whole of this affair. Having been appealed to by their unfortunate *confrère*, they assemble immediately in great numbers, express their sympathy, make up a handsome subscription, and write a letter, as with one mind, condoling with M. Noroy, and stating very decidedly their views of the responsibility question. We gave a short history of the circumstances of the case in our last number but one, and have great pleasure in appending to our present remarks the spirited letter of our Parisian brethren.

Our readers will recollect that the conduct of M. Chonippe, the *officier de santé*, was much canvassed, and severely handled by some of the speakers at the first meeting in Paris. There is a distinct paragraph in the letter devoted to the subject, and a quotation from the laws is introduced, which bears heavily on the adversary of M. Noroy. It is to be regretted that matters have been suffered to go this length: personalities might better have been avoided; and we are not the less willing to say so, as we inadvertently allowed ourselves to be carried away, in the first instance, by the opinion of the majority, but are now sensible that the resolution taken by the larger portion of the assembly, was hasty and incorrect. It only affords another proof that masses of men may be swayed just like individuals, by partial feeling and one-sided views, when the passions become

mingled with the judgment. M. Chouippe will no doubt have his revenge: he can retort upon his opponents, that they have *suppressed the law* in giving a garbled quotation. It is a remarkable fact, however it has happened, that in the quotation given in the fifth paragraph, a most material qualifying point has been omitted. The law certainly says, that no *officier de santé* shall undertake a capital operation without the advice and consent of a doctor graduate: but then it adds—"if there be one in the locality." Now this important addition to the clause was overlooked by some zealous advocate of the Noroy cause; and in the drafting of the letter, in which several clever men were engaged, it would seem that nobody even suspected the omission. It cannot be supposed for a moment that it was intentional, or that there was a suppression: it is only curious that it could have occurred, and to be regretted, as it may afford a handle for retaliation to the adverse party. It appears that there was *no* doctor graduate practising in the same locality with M. Chouippe.

With this little exception, which unfortunately in a deliberate document of the kind, *volat irrevocabile*, we can see nothing in the letter which is not highly to be approved of. Its temper is calm; its tone is decided; and it will be observed that the great body of practitioners in the French metropolis no longer insist on that abstract and absurd principle of irresponsibility so rashly supported by some wild reformers among them. They distinctly enjoin obedience to the laws; they refuse to allow the medical man who has transgressed wilfully or by culpable neglect, to shield himself beneath any supposed professional privilege; but they as decidedly deny the right of judges and common juries to take cognizance of what is only properly cognizable at the bar of public opinion.

We do not pretend to be adepts in the law of France, but our impression is, and we have reason to believe, that medical practice is much more unprotected in that country than among us. Here we suffer quite enough, heaven knows, from the inroads of quacks and unqualified pretenders; but if, on the one hand, we are less screened than our neighbours from the intrusion of such gentry, it must be allowed, on the other, that the state of our law is much clearer than theirs, with respect to medical responsibility. What they contend for so earnestly, we enjoy. No qualified practitioner (unfortunately but too often no *unqualified* one either) is ever meddled with for malpractice, unless it can be shewn to have originated in culpable ignorance or neglect; and "no physician or surgeon who gives his patient a potion or plaister to cure him, but which, contrary to expectation, kills him, can be convicted of murder or manslaughter: it is simply held to be a misadventure*." We are, however, certainly exposed to one serious provision, made and ordained by the wisdom of our ancestors, of which we might complain, perhaps with as much reason as our French brethren, did not the spirit of the age operate in keeping it in great measure in abeyance;—we mean, that by the law of this land, we are liable to the imputation of a great misdemeanor and offence, if our practice be unsuccessful in any case, and it can be proved that the catastrophe was the issue of an *experiment*. This, as it is justly observed in the subjoined letter, is opposed to all improvement in the healing art, and the consequence would be fatal to the best interests of humanity. But our public have long felt what the French say theirs ought to feel—namely, that the enforcing of such a law must put in jeopardy three important objects—"sufferings to be relieved, diseases to be cured, and life to be prolonged."

* Blackstone.

A late writer on the laws of the medical profession in France*, takes a very sensible and straightforward view of the question. In his chapter on medical responsibility, we find him arguing as follows: "When the medical man acts with zeal and forethought, and under the inspirations of his prudence and his best ability, it were unjust and absurd to call him to account: he is only answerable to his own conscience. To maintain the contrary, were to aim a heavy blow at the progress of medical science, and to degrade the medical profession. Why not, by parity of reasoning, make barristers answerable for the issue of the causes entrusted to their care? The circumstances are perfectly similar." M. Trebuchet then alludes to the case of Dr. Helie, and the first part of that of Thouret-Noroy (both now on record in this journal), after which he proceeds:—"It is impossible to read this judgment without being strongly impressed with the difficulties entailed by the doctrine of responsibility, and the false position into which it throws the tribunals which act upon it. But let us not be misunderstood. We are most ready to admit the principle whenever it bears on facts which all can understand, or infringements of the laws beyond the reach of misconstruction. Thus we would not hesitate to enforce it in the case of a medical man who should prescribe or operate in a state of drunkenness; or where a surgeon suffered his patient to die of hemorrhage after amputation, through an unwillingness to call in a professional assistant; or where a physician ignorantly writes a recipe that despatches his patient; or where a medical man, in pressing difficulties, refuses assistance, &c. &c. On the same principle, a notary becomes liable if he has omitted the requisite forms in a legal document: an advocate

also is liable in this sense—and so are the judges themselves. With what show of reason, then, can it be argued, that in grave offences which can be appreciated by all—where a mother, a wife, or a child, has been carried off—that there the business should end; the medical man should take his fees, and leave us to our sorrows? This surely would be to exempt the medical profession from the natural laws that bind society."

We are well pleased to find such sentiments freely advocated by an author of so much talent and integrity; but still more so to perceive that the medical practitioners of Paris, as a body, liberally adopt and avow them. Here is their letter:—

To Dr. Thouret-Noroy.

SIR AND RESPECTED BROTHER,

YOUR appeal ought to be listened to by every member of the profession.

The honourable step taken in your favour by the Provident Society (*l'Association de Prévoyance*), and the eagerness with which other medical men have followed their example, are decisive, if we only understand aright the bearing of the struggle in which you are involved.

But there are two distinct considerations, sir, in this affair of yours: first, the particular fact in which you are immediately concerned; and, secondly, the general principle of medical responsibility.

With respect to the first, in addition to what has been decided by the medical men of Rouen, we should say in the most unequivocal terms, upon examining the law process altogether and in detail, that we have not found any documents which would be conclusive for conscientiously convicting you; yet *we* ought to be, in such a matter as this, the most enlightened jury, and the most competent judges.

We deplore the absence of certain elucidatory testimony, but feel that it would not have been wanting for the information of the judges, in so important an affair, had not M. Chouippe, *officier de santé*, failed in the first instance in the observation of that propriety which is required of all the mem-

* Trebuchet; *Jurisprudence de la Médecine en France*, 1831.

bers of the profession—the demanding a consultation in a case of difficulty: and, in the next place, had he not infringed the law of the 19th *Ventose*, year xi., which is to this effect:—“That no *officier de santé* shall practise any capital operation, except under the inspection of a graduate doctor.”

But supposing for a moment, (which, however, is far from being proved,) that there was an aneurism in question, the principle of medical responsibility would still clearly not be applicable; and this leads us to the second point under consideration.

With regard to the principle of medical responsibility generally, we will be bold to say that it is nowhere written in our laws, and that it has never been acted upon, except in some few instances, by extension,—by analogy. Is it possible to suppose that such a principle would have escaped modern legislators, when it is traced in letters of blood in the Roman law? No; and if we ask Montesquieu the reason, he tells us: “The Roman laws were not made under the same circumstances as ours: at Rome any one might meddle with medicine that would; but here medical men are obliged to study, and to take degrees; after which they are supposed to understand their art.”—(*Esp. des Lois*, xxix. 14.)

We shall not, however, avail ourselves of the fact, that medical responsibility is not written in our laws: were it even written in common sense, we should be the first to demand its application; but we must say, on the other hand, that if the principle be once admitted, the free, conscientious, progressive exercise of the healing art is rendered impracticable, and humanity is left in continual danger. Society, in truth, more than we, ought to dread seeing the medical man placed in the cruel alternative, either of remaining in a fatal inactivity, abandoning his patients to the certain consequences of their complaints, through a regard for his own safety, or attempting their cure by operations, salutary no doubt, but of such a nature that in certain cases, which can neither be calculated on nor foreseen, he may compromise his honour, his reputation, his fortune. It is, therefore, not science merely, nor the medical body exclusively, which would suffer by the arrangement, but the community at large would find itself inces-

santly trammelled in the threefold object of—sufferings to be relieved, maladies to be cured, and life to be prolonged.

Let us observe, however, that there is no wish on our part to interfere with the operation of the laws with regard to medical men who may have betrayed bad feeling, inadvertence, guilty purposes, or criminal error, in the discharge of their duties. Every offence committed in the exercise of our profession ought to be punished with so much the more severity, as through that very exercise the evil-disposed have the more facility in the execution of their plans. It is evident that all misdeeds, which cannot be reasonably attributed to the uncertainty of medical science and the difficulties of the art, ought to be punishable; but all others are only cognizable at the tribunal of public opinion.

In general, that happy instinct which animates the numerous reunions of enlightened men, does not recognize error in facts which awake in all the same sentiments and the same sympathy. It is accordingly, sir, at once our duty and our happiness to announce to you the resolution adopted by this assembly, that you should be apprized by proofs, material and moral, of the interest universally excited among us by your unhappy affair; and we are flattered, sir, by having this opportunity of transmitting to you the creditable expression of our feelings.

THE MEDICAL PRACTITIONERS OF PARIS.

Signed, on behalf of the meeting, by
the committee—

MR LISTON.

WE understand that an operating surgeon for the London University Hospital has at length been procured, in the person of Mr. Liston, of Edinburgh. It was said very lately that Mr. L. had declined the offer, and that he had it in contemplation to join a new school at Westminster Hospital. We believe, however, that some difficulties regarding the arrangements in Gower-Street have been got over, and that the above appointment has actually taken place.

CLINICAL LECTURE
ON AMPUTATION,

*Delivered at the Middlesex Hospital, October 11,
1834,*

BY SIR CHARLES BELL.

I NEED not say, gentlemen, that I am happy to meet you again.

The chairman of the Committee of the House of Commons, lately sitting, on our profession, put this question to me, and obviously with that tone which shewed that he expected my ready acquiescence:—"Do you think that the knowledge of the members of your profession, at the present day, is greater than formerly?" This question made me reflect upon my early days, and to remember those to whom I was indebted for education; and as I had had the pleasure of sitting before Drs. Black, Mongro, Rutherford, and Gregory—and, at a later period, the higher gratification of being the intimate friend of Mr. Abernethy, and of consulting with Mr. Cline, not to speak of my earliest and best instructor—this question very naturally brought me to reflect upon the eminence of these men, and mentally to ask, who are in their places now? In short, gentlemen, I believe I spoke correctly when I said that the knowledge of our profession is more diffused now than at a former period, but we shall look around in vain for such men as I have mentioned; and this touches you very closely, because you have not such authorities to look up to as I had in early life. You have not the example before you of men having the same sway over the profession, or who have as sedulously given themselves up to its improvement, and to the teaching of it. You have a greater number of authors (I do not speak of lecturers), whose age and opportunities hardly permit a knowledge of what they write upon; yet who deliver themselves with a freedom and decision that mislead you. I like to see young men doing that which young men can do best, where the eye is acute and the hand steady; investigating into structure—anatomists—an employment which becomes them; but it is far otherwise when young men take up practical subjects with the air of authority of an old practitioner, and lay down a rule with that decision which few of the oldest are entitled to do. I say, therefore, you enter the study of your profession with this disadvantage: you cannot distinguish, among the papers and pamphlets that treat of matters of practice, who it is that deserves your confidence; you have still to learn in what authorities you may confide.

I offer myself to your assistance as your friendly commentator, both on the cases that occur and the questions that are rife among you: one who has, I believe, more years' experience than any who now take an interest in the studies of our pupils—one who has never distinguished himself by extravagance and the mere love of novelty, when life and death are in the balance.

I am very desirous of addressing to you some observations upon *Cancer*, which I feel I am bound to do: it was neglected during the whole of last year. It happened some years ago, that on a certain day a gentleman came into this hospital and gave 6000*l.* for the establishment of a cancer ward. On the death of Mr. Whitbread, it was discovered that he was the benevolent and munificent donor. From that time, then, to this, we have had a succession of patients in the last stage of this disease, and the reputation of the hospital in that respect has brought a great many private cases, of the same kind, under the observation of our surgeons; and although we cannot give such sums of money, yet we are bound, under the same influence which actuated this benevolent gentleman, to do all we can to make this part of our charity useful. With that view, I will, through you, and in effect to extend the benefits of it, take an early opportunity of presenting you with some of the records of this hospital, and drawing your attention to the subject.

AMPUTATION.

In the meantime I shall offer you some observations on the subject of amputation, because there is no part of hospital practice that will better accord with those principles which are inculcated in the early part of a general course of surgery. This is a subject that brings you to reflect upon those processes of inflammation which are the precursors of adhesion—brings you to reflect upon what are the impediments to adhesion—brings you, in short, to consider the constitution, as well as the state of the part. Besides, were we to enter upon the *question of amputation*,—that is, the various occasions of performing the operation—there is none which embraces so large a portion of a general course of surgery, or which impresses you with the importance of your art: you must entertain many difficult questions before you can make yourselves masters of this. I find, then, before me, a note of the following cases. The first is,

Fracture from an Accident on Railway, compound, and complicated by loss of blood.

In this case, the joint was not only cut into, but the cartilage on the end of the

femur was peeled and folded back, giving proof of the great force employed.

I will not detain you, at present, with a definition of compound and complicated fracture; but the reflection I make upon the subject is, that in consequence of these vast improvements in machinery, and the multiplication of them, and of a new power, as it were, being brought into operation, acting with more than the force of gunpowder, the country surgeon cannot escape from those oppressive questions which assail the army and the hospital surgeon: he must prepare himself to say what is to be done in these tremendous accidents. I was lately at Liverpool, and the party was very desirous of seeing the railway; I was satisfied with seeing one effect of it, for, on going into the hospital, I found a man, just brought in, actually divided; a workman who, although he had been upon the railway from its commencement, yet could not calculate the rapidity of motion in the machine; but happening to look a little to the right, the engine came upon him to the left, which cut his thigh obliquely across, and also his pelvis, and so mangled him that he lived only three hours. These railways being about to be formed all over the country, it is an additional reason why you should take into serious consideration what is to be done in these severe accidents, where not only the parts are laid open, and the bones fractured, but where the surrounding parts are benumbed and injured by the extraordinary rapidity with which the weights are impelled.

The next case is,

Fracture, with Compound Dislocation, of the Wrist, and Mortification.

This case you have just seen; and I remind the younger students that this is what is called the *humid gangrene*, in opposition to, or contrasted with, *dry gangrene*; the latter being the spontaneous mortification of the extremities, which comes from disturbance or weakness of the constitutional powers. Such a mortification as you have now seen is rapid—is attended with extravasation of fluid, with emphysema; the air of putrefaction extending through the cellular membrane. It is wet, cold, and flabby; and presents a totally different appearance to dry gangrene.

There is a sort of rule of the profession, that when you have to operate on a case of mortification, you should not do it until there is a line of demarcation—a line of inflammation which marks the power and disposition of the living surface to separate from the dead part. The meaning of it is, that you are to look for that effort of the constitution which shews a disposition and a capacity to throw off the dead part.

The surgeon's knife is required to remove the dead part, to aid the constitution in its attempt; and when he does that in these circumstances, he has no apprehension of mortification coming upon the stump. But if the mortification be progressive, and result not directly from the injury, but from the state of the constitution, and the limb be then removed, you find mortification will shortly take place on the stump. In the present case there is a consultation as to the propriety of immediate amputation, and I say, "lose not a moment." You have two powers here to consider. As to the patient, he is a poet, or rather an opium-eater and a poet: he throws himself over the window; and all this implies there is a great disturbance of mind, and it might be presumed a great deterioration of the powers of life. The mortification, then, takes place partly from the injury and partly from the constitution, and it is just one of the cases that gives rise to the important question, whether we can venture to amputate, without the danger of mortification coming upon the stump. I say, for my own part, I am for immediate amputation; because, although I see that the emphysema is spreading, and the mortification progressive, yet I trust that so large a share of the cause of mortification is in the accident itself, that, with due attention to the patient's constitution, he may rally, and the stump remain free from mortification. But more especially I am induced to amputate immediately for this reason, that I know, in the condition of the limb now presented to us, if it be permitted to remain, absorption must take place from the mortified parts by the living surface. You will observe that there is a great line of contact between the mortified and living part; the latter absorbs the putrid matter, and then the patient sinks rapidly; not, as it were, the direct consequence of mortification, but the effect of absorption of the putrid matter.

I cannot touch upon this subject without reminding the younger surgeon of the possibility of his mistaking ecchymosis for mortification; for in such accidents, the blood is sometimes so extravasated into the cellular membrane, and the skin is so gorged and injured, that life is lost in it; and from its death you would imagine that the limb was altogether mortified. I have mentioned humid and dry gangrene, and I remind you that surgeons mean by *sphacelus* the entire mortification of the limb through and through, so that from the surface to the bone it is dead, and in a state of chemical change; for you see it is possible that the outer parts of a limb may be mortified, while the muscles and the internal parts possess life. You must be careful,

then, to distinguish the effect of a bruise, attended with extravasation of blood and mortification of the skin, from a case of true humid gangrene, where the whole limb is affected: the one being purely local and superficial, the other formidable, and more or less constitutional.

Compound Fracture of the Tibia.

The third case here mentioned, is one of compound fracture of the tibia; "comminuted, bruised into portions; a part of the tibia is removed; bleeding;" and this latter circumstance it is which makes the complication. On the fifth day, three quarts of blood were lost in two or three minutes; which implies that a large vessel—the posterior or anterior tibial artery—was torn by the bone. But I must remind you that we have very considerable difficulty in practice, in saying whether the blood proceeds from the larger or the smaller artery—that is, from the anterior or posterior tibial artery, or from the nutritious artery of the bone; because, when the bone is split, and the nutritious artery opened, the latter is in very peculiar circumstances—it is not permitted to contract, and it bleeds day by day so profusely, that you would be very apt to conceive that the hæmorrhage proceeded from the large artery. I remark the fact, without, at present, entering into any disquisition upon the cause; but just as you know that a person will actually bleed to death, in some circumstances, from the drawing of a tooth, so you may understand that much blood may be lost from so small a vessel as even the nutritious artery of the tibia.

The next case on the list is one of

Fracture into the Ankle Joint.

Very severe pain and excessive suppuration took place in the injured part; at length it was obvious that the wound communicated with the joint. Amputation was therefore performed. The stump granulated, but with much of discharge. The patient suffered great emaciation; the lungs became affected, and he died five weeks after the operation. I hope, then, many of you anticipate what I have to say on this head. When you are thinking of amputation, or of any great operation whatever, you must remember that there is no performing so formidable an operation as cutting largely, and exposing an extensive surface, which must inflame, and most probably suppurate, without producing a corresponding condition of the whole system; and that if there be, as it is vulgarly and yet truly expressed, any weak part in the constitution, this general state of excitement and fever will fall, with accumulated influence, on that part; so that if a man have a disposition

to phthisis, and suffers amputation, you will immediately find an aggravation of all the formidable symptoms, and ten to one but he dies, as this man did, from a large abscess in the lungs. It is the same in any great operation as in amputation. The idea has been, that by cutting off so large a portion of the body, more force of circulation was given inwardly—that the powers of the circulation became too great. That is not the rationale. The fact is, the inflammatory process and fever produce an action on the part disposed to disease, and if that part be the liver, kidney, bladder, or prostate, it will be very apt to be influenced—to become the seat of inflammation and suppuration. Hence you see how important it is, in all questions of amputation and of great operations, to see justice done to the patient and to your own characters—to see that the patient has no disposition to local or internal disease. Sometimes you cannot suspend the operation; but if you cannot withhold the hand, yet take some friendly advice upon it, and let it be understood that the danger incurred is foreseen, and is unavoidable—that you see it, and would ward it off if you could. This touches the case that I spoke of as I went round the hospital yesterday. A man comes in with a fistula in ano: it is very easy to operate, but, on looking at him, it is evident that the local disease belongs very much to his constitution—that there is a disposition to disease in the mucous membrane generally; and you are accordingly directed to symptoms, and find that there is a complaint in the chest. No doubt, if the surgeon with a bold hand, and in a thoughtless moment, had resolved to cure the man by an incision in the rectum and anus, cough, shortness of breath, inflammation, pain, and probably death, would be the early result.

Compound Fracture of the Leg—Trismus.

In this case, a man is thrown from his coach-box: the consequence of which is a compound fracture of his leg, "spasm, suppuration never fairly established, discharge sanious, and, on the fifth day, trismus." This brings you to consider the question in another aspect. A consultation is held, and it determines that amputation shall be performed, but before the man can be carried into the room he dies. Here is a lesson not to be forgotten. Remember that a man with trismus, having suffered for two days, and on the third day seeming to be much better—to be much relieved from his spasms and his sufferings, and capable of opening his mouth—is, in fact, about to die. Do not be thrown off your guard by these apparently favourable circumstances, and say to the friends he is now relieved—he can swallow, he can open

his mouth, he is no longer shaken by these violent spasms, he is obviously better—when in half an hour he may be dead. Of course the same observation touches the question of amputation.

CONDITION OF THE STUMP.

Neuralgic pains, &c. after amputation.—The next head of inquiry is also a very important and practical one; it refers to stumps after amputation, and neuralgic pains. You have seen the surgeons consulting on the condition of two patients, the question turning on the state of the stumps. I would ask you, is it worth your while to consult with a man who makes wooden legs? After all, is it not your desire that the stump should be such a one as can be put into the socket of a wooden leg? I fear we are a little negligent in this. We are very anxious to save skin, and there are good reasons for it; but remember, if you save too much, and have a loose flabby stump, it is not a good one, or at least the maker of a wooden leg will not allow it; it gives him a great deal of trouble to satisfy his employer, and to enable the patient to rest on the wooden leg. It is essential, then, to save skin, but you must save it with a certain reflection, viz. that you must form a firm stump, and not a loose or flabby one.

But another question is much more important with regard to stumps, and that is, the condition of the extremities of the nerves. Let me remind some of you, that last season I called you back to the consideration of this matter*, as by far the most important which comes under the head of amputation; for I know no suffering greater than that which results from the stump after amputation, when the nerve is engaged in the cicatrix, or when it is laid over the extremity of the rough bone.

Another question under this head of neuralgic pain must enter into your deliberations. There is a disease of the knee-joint, for example, which exhibits no formidable appearance outwardly, nay, I may say inwardly, for in the case alluded to there is only a small portion of cartilage detached by ulceration, perhaps just upon the point of the condyle, yet the case is attended with more suffering than those cases of true white swelling which you see from day to day, where the limb is contracted, the joint swollen, and a succession of abscesses form around it. Mark, then, this case of extraordinary pain attended with little seeming derangement of the parts internally, and you will see the necessity of remembering that there are mere neuralgic pains greatly resembling it—that is,

pains (for the term has been recently got up) not proceeding from the disease of the part, but from some condition of the system, or some derangement of the functions, of which you are yet ignorant, but which the greater part of the profession, and I believe justly, conceive belongs to the constitution, or to some internal irritation. You will not be here a season, I am sure, before you are familiar with these. Not to speak of the true *tic douloureux* in the face, you will find such neuralgic pains in the mammae of patients to be sometimes so excruciating, that they will suffer amputation if you please. In other cases there is pain in the testicle, excruciating pain, worse than the *tic* in the face. But the pain is not removed by amputating the organ! So there may be pains in the extremities referable to a joint, yet not in the joint; the patient experiences the pain in the extremity, but the disease is elsewhere. I remember being consulted upon one of these cases, and so were most men of any sort of eminence in town. A very beautiful lady of rank, had a pain in the ankle-joint; it was treated as disease of that joint, and yet I never could discover that there was any puffiness. You are aware that when there is effusion into the cellular membrane and skin, or a puffiness over the part, it is an indication of internal disease; thus you distinguish disease of the bone, disease of the spine, &c. But there never was observed any discolouration, any inflammation, or puffing, of the ankle-joint of this lady, although the pain was excessive. Fourteen years have elapsed, and the pain is there still. She has been married; and the degree of pain she suffered was so great, that this lady was led to the altar on crutches, and moves on them to this day, yet the joint is to all appearance perfect. It would be very wrong to amputate in such a case. The patient would submit because the pain is so excruciating; but if the limb were removed in these circumstances, she would have to complain that it had been taken off, and perhaps buried, and yet that the pain was still in it.

But sometimes the pain resides in the affected part, of which I will give you a curious instance. Baron Driesen, General in the Russian service, received at the battle of Borodino a musket-ball in the lower end of the femur. He suffered much from inflammation of the whole limb, from supuration and fever. All that, however, subsided, but there remained a fistulous opening leading to the ball, which was socketed in the bone. He was a particular friend of the Emperor, and under that character was sent here to have the limb removed, if necessary. I resisted the operation, for I conceived they had kept up a great deal of irritation by means of dress-

* *Vide Med. Gaz.* vol. xiv. page 185.

ing and introducing setons into the wound. I removed these; the wound closed; and I hoped that in this, as in many other instances, the ball being at rest, little inconvenience would arise. I have known a ball, when deep-seated, remain innocuous for ten or fifteen years, then gradually drop down under the skin, when inflammation and suppuration would declare its place. I sent him home; but when in St. Petersburg a person proposed to dissolve the ball by pouring quicksilver into the wound, which had opened again. He did so, and it happened, strangely enough, that this practice seemed to succeed. The wound healed, and the surgeon received a riband of honour, and a sum of money from the Emperor. However, the pains became again excruciating, and under this suffering he came a second time to England, and I think I never saw agony so acute; the pain came like a shock of electricity suddenly plunging into the limb, and so severe that he would faint and fall down insensible from the excess of pain. Under these circumstances I removed the limb; and you will be surprised when I tell you, that on looking at it I found the nerve itself had globules of mercury in the interior of its texture. I was sorry to see this, because I was led to presume that there must be similar globules in the remaining extremity of the nerve in the stump. He went home, and has been a great sufferer with neuralgic pain, which has proceeded from the injection of the theca and cellular texture of the nerve itself with globules of mercury. These "plunging pains" are signs of affection of the nerve. Here is a case in which pain, possessing all the characters of neuralgia, was situated in the part; and so it will sometimes happen, that in amputating, the nerve is left too long; it is folded in upon the bone, or engaged in the cicatrix; and in the very case which is now in the house, we must have to determine whether the suffering of the patient be from the nerve so engaged in the cicatrix, or more purely neuralgic, meaning by the term, pains arising from causes independent of the stump.

In regard to the operation itself, the following are the points you have to consider:—The form of the stump, and the condition of the nerves. As to the first, the thing corrects itself. The lesson is too distinct to be neglected. The surgeon finds that the integuments do not correspond to the face of the muscles, or that the bone projects, and he corrects himself in future operations. But there is a reason for attending to the manner of amputating far more important than this. I wish that your patients may not have a mass, of the size of pigeon's egg, on the

end of the ischiatic nerve, the continued source of pain.

In running over this subject, you will remember that there was a time when the limb was at once divided by a circular incision down to the bone, and that Cheselden corrected it. A question arose between Cheselden and Petit, to whom the great improvement was owing, of making a double incision, first through the skin, and then retracting it, and afterwards cutting through the muscles. The practice was early and effectually established in England, but not so in France; and here is the evidence in favour of Cheselden, and against Petit. The English surgeons, following this method, made good operations, and the French, following their authority, made bad ones; and up to the period of the battle of Waterloo I saw operations performed in which there was a total disregard to the principle which directed the double incision, in which the face of the stump was as flat as a piece of bacon in a pork butcher's shop. There was bone, muscle, and integument, all forming one surface. I would not pretend to take this as an example of the manner of amputating in France; but so it was, that I saw two or three amputations by French surgeons after that great battle, which would have been considered extraordinary exhibitions at home. You will remember that a variety of attempts were made to improve the mode of operating, and that Alanson proposed to avoid the consequences of an improper amputation, by scooping out the muscles, for it was nothing else. After making his incision through the integuments, he carried the knife in an oblique direction, the point rested on the bone, whilst the hand was carried round, by which the incision was completed in all the circle. By this he conceived that the muscles round the bone were cut deeper than those which were more superficial; which amounts, after all, to merely cutting out the flesh of the limb in a shape that would correspond with a conical body. This is clearly bad, because the object is to have the muscles hanging over the bone, and not cut away from it: the bone is never to be seen; the muscles should bulge out and turn over it. It was probably with the same intention that M. Louis, the French surgeon, attempted to divide the muscles by two incisions, dividing first the looser, and then the firmer muscles. That is a loose way of talking to you as anatomists. I have seen this operation repeatedly performed by my former colleagues in this hospital, cutting the superficial muscles, letting them retract, and then cutting the deeper muscles, making thus three circular incisions. But, as anatomists, you know that there are not all around the limb a superficial and deep class of muscles. You

may, if you choose, so manage as to cut the vastus internus and vastus externus, and leave the cruralis; but what comes of the muscles on the back of the thigh? There is an anatomical reason for dismissing this mode, and there is an exceedingly good practical reason too for it; it is cutting away the muscles from the bone, and making a haggling irregular surface.—Lastly, Desault with the same view passed the knife as you have seen it lately passed, making a double flap; not a circular incision—not cutting the skin first, but putting down the sword-pointed knife through the limb, so as to transpire it, and drawing it obliquely down, first on the inside, and then on the outside, so as to form two flaps. This being the operation performed by my colleagues of late, yet being Desault's operation, and one I have often reflected upon, I may be permitted to repeat my objections to it, objections not arising from what we have just seen, where the operation could not be better performed, but to the manner as practised by Desault. I think it forms a very irregular surface, and that although you may say the operation is quickly done, yet the patient is not quickly off the table, for you must have observed that there is a difficulty in taking up the arteries. Why so? Because of the irregularity of the muscles. When the muscles are divided at once, either directly or obliquely, but from without inwards, the arteries project more distinctly, and the bleeding is more free; but in this mode you must have observed the irregularity of the surface, and that the muscles obscure the mouths of the arteries.

Let me tell you incidentally, that you are not to look to the centre of a muscle for an artery. You have been in the dissecting room; and let me ask, did you ever find a large branch in the centre of a muscle? You look for an artery, such I mean as requires the ligature, in the interstices of the muscles. You know what are the branches of the profunda, where they should run, what position they are in with regard to the bone, between what muscles they lie,—such is the use of anatomy; but if you merely take the face of a stump, as some of my early acquaintances would have done, and look to what vessel is bleeding, and tie it, you will be pricking and taking up vessels that are bleeding on the surface of the muscles; and just when you are about to dress the stump, there comes another gush from a great branch in the interstices of the muscles. You must take it anatomically, and look where you know the branches of the profunda, or R. anastomaticus lie, among the cellular interstices of the muscles. This by way of parenthesis.

I was about to say, when you meet with

a certain difficulty in finding the arteries upon the stump, from the irregularity of the muscles, what is the state of the nerve? I cannot allow this to escape my observation; for of all the conditions to which man is subject, there is no state of suffering more severe than that produced by the engagement of a nerve in a stump; and therefore I say it is most important that the nerve should be directly divided across, and not obliquely torn out. You cannot secure this effect unless you make a free and decided division of the muscles. When you pierce the limb with a great outline knife, and put it close on the bone, and draw it out obliquely to make the flap, you cut the nerve longer than the other parts. The nerve is firm, but very elastic; it is not so easily cut through as the muscles. Being so elastic, it goes before the edge of the knife: and if you look carefully to an amputation performed in this way, you will find that the nerve hangs out; that it becomes necessary to draw it out and cut it again. What do you say to cutting the nerve a second time, by way of proof that this operation is attended with less pain! You now understand my objection to this mode of operating. I do not object to it as being a butcher-like operation, I could get over that; but my objection is, first, that the nerves are cut irregularly, and left long; and secondly, that although the two first incisions are done with great dexterity and facility, yet the operation is not so quickly over as in the mode by double incision.

The common operation is to be performed with very little deviation from what is universally recommended, and is to be conducted thus:—If you draw your knife directly in the circle, you will find that the ends of the skin will not fall neatly together; that is of no great consequence, still it is as well to find the surface so nicely cut, that it falls together like a hare lip. To insure this you have only to give the knife the slightest inclination, and to form a semilunar cut or flap on the outside, and when you bring it round on the inside to do the same; so that instead of there being a perfectly circular incision, there is a little deviation—two flaps, one on the inside, and the other on the out. This is done easily, and without ever lifting the knife, so that the looker-on hardly observes that you have in any way deviated from the simple circular incision. The effect, however, is, that the skin falls over the face of the muscles, and unites in a line.

In the next place, you are not by any contrivance to cut the muscle away from the bone. With respect to the operation for amputation of the thigh, it is the easiest thing possible. When you have cut the integuments, and your assistant has

retracted them, you place the knife close to the edge of the retracted integument, and with a sweep carry it down to the bone, and in the entire circle. This makes a uniform surface. But now let the assistant raise the limb up, till the femur comes into a perpendicular position, and then you find the muscles fully retracted, and a large portion of the bone exposed. You now saw the bone horizontally. When you have done, you just see its cut surface; and when the stump is brought down, you see it no longer, and you never ought to see it again; for if you do, it is a bad operation. If you perform the operation with the limb kept horizontally on the table—if you retract the muscles, however carefully, by a split cloth, and not by position—and if you then cut through the bone, as near the muscles as you can, no sooner is the bone divided than up cocks the stump and out pops the bone. It is so easy to demonstrate this on a black board—it is so obvious in itself—that I am surprised that this simple rule should be omitted. Divide the muscles; and when this is done, take a little time—do not hurry—inform your patient that the pain is over, raise the limb, retract the muscles with your apparatus (a split cloth is the best), and then divide close to the muscles. When the limb is up, the bone perpendicular, and the saw horizontal, the effect of it will be to have no splinter of the bones; and I say again, you will just see the surface where you have divided it, and when you bring the stump down to its original position the muscles have all fallen over the extremity of the bone. The muscles covering the bone, and the integuments falling nicely over the muscles, not only have you an amputation well performed in respect to the adhesion and early cure, but you have, according to my conception of it, an amputation performed with the highest possible regard to the deep burying of the extremity of the nerve; which I repeat, once for all, is by far the most important circumstance to which you can attend in an amputation.

FALSEIFICATION OF WRITINGS.

A MEDICAL student was recently convicted and punished in France, for forging a will, by altering the handwriting; and it is said that frauds of this nature are becoming alarmingly frequent in that country of late. We should not be surprised if similar attempts were made here ere long by some of our *chevaliers d'industrie*; but fortunately the mode of detecting falsifications of the kind is not difficult, if suspicion be once awakened. Old writing is removed, and place made for new, either by erasure, by the application of muriatic acid, or by both. A supposed erasure should be examined with a magnifier; and if it seem to

have been touched with size or sandarac, as a ground for the new writing, these substances may be dissolved with water or alcohol respectively. If muriatic acid have been used, it is not unlikely that all the acid may not have been washed out, when the excess may be readily tested with litmus paper. But whether chlorine or muriatic acid have been employed, it is probable that some traces of the oxide of iron of the old ink may still remain; and these may be rendered visible by washing the part with a camel-hair pencil, dipped in diluted gallic acid. The latter process may have to be repeated several times, and on successive days, allowing the dilute acid to evaporate slowly each time. We are indebted to a paper by M. Chevallier, in the last *Annales d'Hygiène*, for these brief but valuable suggestions.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday the 16th October, 1834.

Richard Brownlow Barlow, Blackburn.
Robert Gledstanes Carey, Guernsey.
Charles Henry Cornish, Taunton.
George Jameson, Edinburgh.
Robert Marsh, Bath.

NOTICES.

Professor Mayo's first lecture on Pathological Anatomy shall appear next week.

We shall be glad to have the papers to which our Dublin correspondent alludes. The one received will probably be given in our next number.

LECTURES

ON

DISEASES OF THE CHEST,

In the course of which the Application of

PERCUSSION AND AUSCULTATION

ARE FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE IV.

THEORY OF THE SIGNS OF DISEASES OF THE LUNGS—(continued.)

EXAMINATION OF THE SIZE, MOVEMENTS,
&c., OF THE CHEST.

I now proceed to the consideration of some other signs of disease of the chest, which we shall class under the following heads:—In the first place, those derivable from the touch; secondly, from the examination of the external parietes of the chest; thirdly, that from pressing the abdomen, a means imagined by Bichat; and, fourthly, of the mode of measuring the capacity of the lung, proposed by the late Mr. Abernethy.

EXAMINATION BY THE HAND.

First, with regard to touch. The sign afforded by the touch generally gives to the physician but very insufficient data; the hand is infinitely more important to the surgeon in detecting disease: however, we derive some advantage from it, particularly in affections of the abdomen. Thus we can discover peritonitis, and determine its extent, its situation, and, indeed, its degree, by the amount of pressure which the patient can bear. When the liver or the spleen are enlarged, we can determine, to a certain extent, their volume, by the hand. Dropsies, or tumors formed in the mesentery, may be detected by the same means. Upon one

occasion, I ascertained by the hand the presence of a calculus in the pelvis of the kidney. It was in a very thin subject. Certain affections of the uterus may frequently be distinguished by the touch; and, in fact, it is much more easy to distinguish diseases of the abdomen by the hand, in consequence of the softness and pliability of its parietes, than the diseases of the lungs, surrounded, as those organs are, by the comparatively unyielding surface of the chest.

There are, however, some signs of diseases of the lungs that may be derived from touch. Thus, for instance, if a person, with a very grave voice, speaks or sings, upon applying your hand to the parietes of the chest, particularly at the upper part, you will very distinctly feel a vibration all over it; but it only occurs in persons with a large chest, and in whom the voice is grave. Can we make use of this sign in diseases of the lungs? To a certain degree we can. You may be sure that wherever you feel this vibration, the lung is permeable at that part, and therefore it is useful as a confirmative sign. On the other hand, you must not conclude that, because you do not feel the vibration, the lung is not sound, unless there be some other symptom indicative of disease: as, if upon percussing a certain part, you have a dull instead of a hollow sound, and are thereby led to infer the existence of disease, then, if on applying the hand, you do not find a vibration, you have a confirmative sign of the impermeability of the lung. In empyema, the touch occasionally is of use. Suppose a collection of pus commences in the cavity of the pleura, and makes its way between the intercostal spaces, forming a projection between the ribs, you can then feel the tumor; and if, on pressing it, the fluid recedes, and then, by coughing, the swelling returns, you ascertain the nature of the affection by the tact. Sometimes a large cavity will form in the apex of one

or other of the lungs, which we call a *tubercular excavation*; in the first instance, this cavity is not complete, but is usually traversed by a number of bands, of pulmonary structure, not yet destroyed, and in this state it has been called a *multi-locular cavity*. When this multi-locular cavity is near the surface of the chest, the matter contained within it becomes entangled, and every time the patient coughs, the secretion strikes its sides, and gives a feeling of gurgling, which gurgling may be distinctly felt by the hand [a preparation shewn of a multi-locular cavity, which produced this sign.] Again: there is a sound with which many of you are perfectly familiar—the deep sonorous wheeze, or rhoncus—which is heard in chronic catarrh. This sound is so loud and intense, that it communicates a vibration to the parietes of the chest; so that it is a common practice of mine to pass my hand round the patient's body, and to make him take a deep inspiration, for the purpose of determining the extent of this species of rhoncus. I do not recommend you to employ this means alone, because the stethoscope will determine the affection much better. *Emphysema pulmonum*, a disease which we shall see consists in a permanent dilatation of the air cells, or in the infiltration of air into the cellular substance which divides the lungs into lobules, often communicates a crepitation to the parietes of the chest, which may be felt by the hand; it is a crepitation like that which a thin dried bladder would give upon pressure. The *fluctuation* upon movement in cases of pneumo-thorax, with effusion into the cavity of the pleura, can readily be detected by the tact. Aneurisms of the thoracic aorta, when they form external tumors (of which there is an enormous specimen on the table), may be distinguished, of course, by the same means.

MOVEMENTS OF THE CHEST.

We now proceed to the examination of the signs to be derived from observing the parietes of the chest; and, first, in relation to its movements.

There are three diseases by which that state of respiration is produced which we have called *incomplete*, a state in which the ribs may be seen immovable on one side of the chest, and moveable on the other.

The first case is that in which an accumulation of fluid takes place in the pleuritic cavity of one side; the lung then becomes compressed by the increased secretion against the vertebral column, so that it is often reduced to a very small volume; the respiratory act ceases on that side; the ribs are there then consequently perfectly quiescent, while you will see on

the opposite, or healthy side, that they move with a rapidity proportionate to the dyspnoea.

The second case is that of very acute and extensive pleurisy; the patient then experiences great pain during the act of inspiration; he consequently avoids elevating the ribs on the side affected, so that they become immovable, or nearly so. This may be easily distinguished from effusion, inasmuch as in acute pleurisy the disease occurs suddenly, and there is much pain, neither of which happens when effusion takes place; and in the latter case also the diseased side of the chest becomes enlarged.

The third instance of incomplete respiration arises from rheumatism of the muscles of the chest, or, as it has been called, *pleurodynia*. Such is, then, the pain occasioned by throwing the inspiratory muscles into action to elevate the ribs, that the patient avoids doing so as much as possible, and breathes only by the healthy side. This state may easily be distinguished from the two others by the pain being increased by elevating the arm of the affected side, by the patient not bearing pressure upon the ribs, and by co-existing rheumatism of some of the other muscles of the body.

DIMENSIONS OF THE CHEST.

Let us now examine the chest in relation to the capacity of its two sides, for differences may occur in that respect, rendering most important signs. We will proceed to explain the causes of these differences; and first of

Dilatation of one side of the chest.—We shall see, when we arrive at the subject of pleurisy, that in the second stage of that disease, more or less fluid is accumulated in the cavity of the pleura; sometimes the quantity is very small, sometimes it may amount to many pints; I have seen as much as nine pints [diagram].

You cannot but suppose that this large quantity of fluid must produce some effects by its presence upon the parietes of the cavity in which it is contained; and it is to those effects I wish at this moment to draw your particular attention.

The pressure of the fluid will first affect the parts which, from their structure, offer the least resistance; thus the lung, being of a soft and spongy tissue, vesicular in its texture, and filled only with air, diminishes gradually in its volume, in proportion to the accumulation of the fluid; so that at last it is reduced to a very small mass, which is pressed against the vertebral column. In the next place, the heart is driven out of its position by the fluid, so that if the effusion be on the left side, that organ is pushed towards the right,

and its beatings can be heard on the right side of the sternum, and scarcely at all on the left: if the accumulation be on the right side, the heart is pressed still farther to the left. The diaphragm, forming the floor of the cavity, will be forced downwards; but as the liver supports that muscle, particularly on the right side, so much resistance is afforded that the effect of the compression is rarely sufficiently considerable to depress that organ below the margin of the false ribs; it no doubt does so occasionally, but I think rarely. If, however, the fluid be in the left pleuritic cavity, the diaphragm will be rendered permanently convex towards the abdomen, will push forwards the stomach, &c., and form a diffused projection along the margins of the cartilages of the false ribs of the same side.

Observe the effects of the pressure upon the external parietes of the chest: the intercostal muscles are first acted upon; they are pressed directly outwards, so that the inner surfaces of these muscles are projected to a level with the external surface of the ribs, thus effacing altogether the appearance of intercostal spaces, and rendering the whole side perfectly smooth, while on the other side those spaces may be sufficiently well marked; nay, some have said that the intercostals have so projected as to bulge beyond the ribs, so that the spaces have become elevated instead of depressed. I have often sought for this, but cannot say I have ever distinctly seen it. Not only are the intercostal muscles acted upon, but also the ribs themselves; they are pushed directly outwards, so that the transverse diameter of that side of the chest becomes increased, and its capacity enlarged. Nothing is more easy than the detection of this enlargement by the eye: a small difference may be perceived—a difference only of a quarter of an inch in the comparative measurement of the two sides, can be determined. Laennec was satisfied with the appearance alone; but as the sign is rendered more perfect by measuring, I should recommend you always to do so, more particularly as you occasion no pain or distress to the patient.

Mensuration of the chest.—For this purpose I generally use a measure, made of some inelastic stuff [shewing it], graduated into inches and tenths of inches; I apply one end of it to the centre of the xyphoid cartilage, and pass it round to the spinous process of the dorsal vertebra exactly corresponding, observing the number of inches; I then measure the other side exactly in the same way, and note the difference. You may measure also higher up if you will, but I am generally satisfied

with that which I have mentioned. [The mode of measuring was here shewn upon casts.]

Contraction of one side of the chest.—After effusion has taken place from inflammation of the pleura, an albuminous matter separates from the fluid and forms a false membrane, which lines the parietes of the containing cavity. This membrane adheres to the costal pleura, is reflected over the diaphragm, and passes from thence over the lung. It varies considerably in thickness; sometimes it is a mere thin and semi-transparent pellicle, through which the colour of the parts beneath can be distinctly seen—frequently it is several lines thick, and perfectly opaque.

Nature often removes the effused fluid by the process of absorption, or art may effect that removal by the operation of paracentesis thoracis. In either case, in proportion to the evacuation of the fluid, the compressed lung gradually expands, and tends to resume its former volume. If the false membrane be thin, it will dilate with the lung, and allow that organ again to touch the ribs; but if it be thick, it will bind the viscus so completely against the vertebrae that no expansion can take place. Both these are, however, extreme cases; it generally happens that the false membrane allows a very considerable, although not complete, development of the lung.

A beautiful effort of nature follows this state of things; for when the lung cannot farther dilate—when it cannot touch the costal pleura—the whole of the ribs of the affected side fall inwards upon the organ, sometimes sufficiently to reach it; the false membranes of the pulmonary and costal pleura then adhere, and form a single membrane of a fibro-cartilaginous structure.

In these two casts you perceive well-marked instances of this *falling in*, or contraction of the chest. The operation for empyema was performed in both cases. In the smaller one, the measurement before the operation gave an inch and a quarter more on the diseased side than on the healthy. You now see (measuring the cast) that it is an inch less; giving a contraction altogether of two inches and a quarter. The larger cast offers a still greater difference, and the depression of the side is here great indeed.

Consequent upon this depression of the ribs, the shoulder becomes depressed also—the inferior angle of the scapula is lower on the affected than on the opposite side—the last rib also approximates much nearer to the crista of the ilium.

The sternum and dorsal vertebra deviate from their natural positions, as you

may see in these casts. The contraction is on the left side, and the sternum and vertebræ are pushed towards the right; so that the centre of the former bone is not on the median line, and the vertebræ form a curve whose convexity is to the right side also.

ABDOMINAL PRESSURE.

Abdominal pressure was proposed by Bichat. He imagined that we could determine the capacity of the chest by pressing firmly upon the abdomen, so as to diminish the perpendicular diameter of the chest, and see how much the patient could bear before he felt a sense of suffocation. You may suppose that it must be impossible to do this—particularly under disease. Laennec justly remarked, in reference to this means, that we had no right to interrogate nature by putting a patient to the torture.

PULMONOMETRY.

The late Mr. Abernethy proposed to determine the capacity of the lungs by making the patient breathe through a tube, the opposite extremity of which was passed into an inverted jar full of water, placed in a pneumatic trough, and to observe the quantity of water he displaced in the jar. This means looks very pretty in theory, but it is perfectly useless in practice; for some persons, even of large chests, will displace less of the water than those of smaller proportions, from the greater determination of the latter in continuing to expel the air from their lungs; but as it is the comparative capacities of the healthy or disordered states we wish to obtain, how can we possibly know what quantity the individual could have breathed in the healthy condition? It is needless also to state how difficult it would be to force a person, labouring under dyspnoea, to make the experiment; sometimes, too, it would be even a dangerous one.

These are the modes of investigating diseases of the lungs, and I hope you have by this time been able to appreciate their various degrees of value; but we have one more means, of infinitely greater importance, by which we can determine the specific nature of the lesion—viz. by *ASCLUTATION*. But this is too interesting a subject to commence towards the close of a lecture; I shall therefore defer it till the next. I will, however, occupy your time with a few observations on the biography of Laennec.

René Theophilus Hyacinthe Laennec was born on the 17th of February, 1781, at Quimper, in Lower Brittany. His father was an advocate. Laennec was placed, early in life, under the care of two

paternal uncles—the one an ecclesiastic, and the other a physician, Dr. Laennec, professor of *materia medica*, at the secondary school at Nantes.

Laennec very early obtained a reputation for scholastic acquirements, more particularly in the Greek and Latin languages. He used to communicate with his pupils, and deliver his clinical lectures in Latin, for the double purpose, as he said, of familiarizing them with that language, and preventing the patients under his care from hearing his opinion of their cases. He was also much attached to antiquarian pursuits, particularly relating to the dialect of his own province; and nothing seemed to please him more than to meet with a Welchman, for the purpose of conversing with him, and comparing the Armorican with the ancient British tongue.

In the year 1799 Laennec was appointed assistant surgeon in the army of the west, an army directed at that time towards the Morilian, for the purpose of quelling an insurrectionary movement made against the constituted authorities. In 1800 he arrived at Paris to complete his education. It was at that period, in France, and under the consular government, that the greatest encouragement was given to the study of all the sciences, and more particularly to those of medicine, surgery, and all their collateral branches. The professor's chair was then the reward of a hard fought contest, and merit alone could by possibility insure the victory. I trust you will not consider it misplaced if I say, that I hope to live to see the day in this country, when no man shall be permitted to occupy any station in which he has to teach others, without having first passed through the ordeal of repeated examinations—examinations not only of the knowledge he possesses, but of his power of communicating that knowledge. Let me hope that the time will arrive when merit shall be the passport to posts of honour—when we shall no longer be obliged to canvass the suffrages of men who, however estimable in other respects, can be no judges of our professional qualifications—when the present system of election shall be totally abandoned, as a system utterly disadvantageous to the public, and degrading to every honourable aspirant.

It was at that time that the reputation of Corvisart was at its zenith; the force of his example, and the value of his clinical instructions, carried enthusiasm into the minds of all his followers. The star of Bichat, too, was upon the ascendant, soon to shed a new lustre upon the face of anatomy and physiology. Bayle and Dupuytren were the contemporaries of Laennec; and it is no wonder that, with masters like

these, and a genius like his, he should soon be seen among the foremost in the rugged path to the temple of fame.

He gained the two chief prizes in medicine and surgery, granted by the Minister of the Interior through the Institute of France; after which he became a critical writer; and the first work upon which he exercised his talents was Benjamin Bell's Treatise upon Syphilis. Impressed, as he had been from the commencement of his studies, with the importance of morbid anatomy, he began early a course of lectures on that subject, which he continued for three or four years, Dupuytren giving a course of a similar kind at the same period. Laennec was the first in France to describe the adventitious deposit called by him *melanosis*, and also the "*matière encéphaloïde*;" but the latter had been previously made known in England by Burns, under the name of *spongoid inflammation*; by Hey, of Leeds, under that of *fungus hamatodes*; and by Abernethy, who denominated it *medullary sarcoma*. Dr. Forbes raises a question as to whether Laennec had any knowledge of the disease having been previously written upon in England, and he thinks he had not; but considering that there was then a short peace, I think it probable that the French anatomists must have known what had been going on in England.

But it is from the year 1816 that the great fame of Laennec is to be dated. At that time he was appointed physician to the "Hôpital Necker," an institution having similar objects to our infirmary for diseases of the lungs. He had occasion at that period to examine a young female, who he supposed was labouring under disease of the heart. From that delicacy of feeling which every medical man should possess, he did not like to apply his ear to the chest, though that idea first struck him. He recollected at the moment that, as solid bodies have the power of conducting sounds better than air, it would be possible by such a means to ascertain more than could be done by the hand. He procured a quire of paper, rolled it up tightly, tied it, and then applied one extremity to the patient's chest, and the other to his ear. To his great satisfaction he heard the beating of the heart infinitely more distinctly than it could possibly be felt by the hand. A discovery like this was not lost upon Laennec, and he immediately conceived the possibility of applying the same means to diseases of the chest in general, but more particularly to the examination of the voice. He commenced a series of observations upon different patients merely in relation to the latter object. He then first discovered *pectoriloquy* and its cause. With unexampled ardour he continued

his researches; and in the year 1818, only two years after his first discovery, he brought forward his extraordinary work on Diseases of the Chest; a work which, for elegance of composition, for correctness of anatomical description, and for originality of facts, is unparalleled perhaps in the history of medicine.

As you may readily conceive, great opposition arose against his discoveries: his facts were denied, his inferences refused, his instrument ridiculed; and, if it had not been for the manner in which the work was written, for the clearness of his anatomical details, and his personal efforts in proving the facts at the bed-side, no doubt auscultation would have fallen into the same oblivion as the percussion of Avenbrugger had done. Laennec's weak frame gave way under all these exertions, and he retired to his native country. His health to a certain degree became re-established, and he returned to Paris in 1821 to reap the fame of his discoveries, and to extend them. He was shortly afterwards appointed Professor of Medicine to the College of France, and Physician to La Charité. He then prepared the second edition of his work, to which he added the mode of treatment. While executing this task, he again fell into a state of great exhaustion, retired to his native home, and in August, 1826, expired at the age of forty-five years.

Laennec died of consumption, and I have no doubt that he had long believed himself to be predisposed to that dreadful disease. You could not be with him for a very short time without seeing him frequently expectorate, and examine the secretion with great minuteness: indeed, while I knew him, it was his constant habit. No doubt a consciousness of this kind led him to his investigations of pulmonary disease; nor do we find him singular in this respect, for some of the best monographic works we possess were written by authors subject to the diseases they have described. Thus, Corvisart died of disease of the heart; Bayle of an affection of the lungs; Sir John Floyer was himself the subject of asthma. The best work written upon asthma in the English language is by Dr. Bree, himself an asthmatic. These instances might be greatly extended.

Thus, if I be not accused of using language somewhat too ambitious, I would say that Laennec fell a victim upon his own altar; that he suffered the lot of mortality from one of those diseases, the description of which has conferred upon him a crown of intellectual immortality.

CASES OF PHLEBITIS:

With Remarks.

By C. INGHAM, M.D.

Surgeon, 29th Reg.

[Communicated by Sir JAMES MACGRIGOR, Bart.]

A Case of Phlebitis, without apparent organic disease, terminating fatally.

DAVID SHAW, æt. 24, private in the 29th regiment, of healthy constitution and temperate habits, was attacked suddenly on the night of the 19th June, 1832, with a disorder resembling epilepsy, which arose, as facts then shewed, from undigested matter in the stomach. After the abstraction of blood, and free vomiting which ensued, he fell asleep, and on the following day he was quite well again. He took a dose of salts, however; and on the third day he returned to his duty. His arm then became painful; but the bandage, though he felt it to be tight, he left on; and he neglected also to report the uneasiness to the medical gentleman who had bled and attended him.

On the 23d instant, the fourth day from the bleeding, he returned with the detachment to head-quarters*, and came to me, feeling unequal to duty, to shew his arm. The wound was found red and gaping; but, excepting pain, there was no constitutional disturbance. He was sent to the regimental hospital; a purgative of senna and salts was given, and cold applications were directed for the arm.

24th, fifth day.—The state of the arm seemed to be improved: it was less painful, and still the constitution seemed to be unaffected. Cold applications were continued.

25th, 6 A.M.—He was found very unwell. The arm was swollen, and the swelling and tension extended upwards and downwards. Said that he was attacked about two o'clock with rigors, which were followed by febrile symptoms. The pulse was 136, rather small, and unresisting. Tongue white; thirst urgent; abdomen tumid and tense; no stool. An oleaginous purgative was administered, and warm applications were directed to be used constantly to the arm.

In the evening the arm was still painful, and the febrile state remained unaltered. The medicine had not operated. A warm bath, and a purgative injection, and hot linseed meal cataplasms, were ordered.

26th.—One copious feculent dejection after the enema, and a good deal of sleep during the night. The arm was still painful and tense. He felt chilly, yet the skin was hot and dry. Pulse 106, soft and regular; thirst urgent; abdomen softer, and free from pain. The warm applications to the arm were found most comfortable. Full doses of James's powder, and submuriate of mercury, were ordered thrice during the day; warm drinks, and a little sago.

3 P.M.—The arm found hot and painful; some irritability of stomach; abdomen somewhat swollen and tense; pulse 120, small; countenance anxious; thirst urgent. The warm bath and purgative injections were again employed, the antimony omitted, and brandy, largely diluted, administered occasionally.

6 P.M.—Vomiting had ceased since the cordial draughts; arm was less painful; pulse 132, regular. A strong opiate was ordered at bed time, and it was repeated at midnight.

27th.—Slept tolerably well during the night. Rigors came on early in the morning, which were followed by partial heat and sweating over the face, head, and neck. Pulse 112, small; stomach irritable; thirst urgent; countenance anxious; stools feculent; abdomen softer; urine scanty, but of natural appearance. The bath and injections were repeated; wine was ordered every second hour, and cataplasms removed every fourth hour.

28th.—Was delirious, and slept little or none during the night. Pulse 112, small and irregular. Made little or no complaint of the arm. Countenance anxious; bowels slow; abdomen less swollen, and free from pain on pressure. The injection renewed. Opiates were ordered, and the cataplasms continued.

29th.—Had slept at short intervals during the night; but when awake, had been delirious. The fore-arm was hard and tense, the arm less so. Pulse 120, small; thirst very urgent; stomach irritable; tongue loaded; bowels not open. Temperature in the right axilla 103°; in the left, 102°.

* A weekly guard stationed at Grand River, two miles from Port Louis.

A purgative injection administered. Camphor, opium, and the other means continued.

30th.—Arm about the wound scarcely painful, but the fore-arm tense; and two or three red lines were seen in the course of the cephalic vein. Passed a sleepless night, with delirium, vomiting, thirst, and occasionally distressing hiccup. Abdomen swollen; dysuria. Pulse 120, regular; jactitation, lassitude, and anxiety of countenance. Temperature, right side, 103°; left, 104°. One feculent dejection.

A purgative injection was administered, Laudanum and Nitric Æther prescribed, Brandy continued, and Caloplasm.

2 p.m.—Respiration found difficult; face of purple hue; pulse 130, throbbing; delirious, and frequent efforts to quit the bed. Remedies continued.

July 1st.—Had passed a better night, though sleepless. He made no complaint of pain in the arm, and he raised it, seemingly with ease; but the fore-arm was swollen and tense anteriorly, nearly in its whole extent. Pulse 120, regular; tongue parched, red at the apex and sides. Temperature 104 deg. in the right axilla, 102 deg. in the left. Had voided urine, and passed one feculent stool.

2d.—Had been delirious throughout the night. Pulse 124, throbbing; face of a dark purple hue; respiration embarrassed; abdomen tumid, but not painful; frequent sighing and jactitation; tongue brown and parched; thirst urgent; dysuria; no stool.

A Calomel bolus was given. A purgative injection. Cordials continued.

3d.—Moribund; and his death took place at four o'clock the following morning.

POST-MORTEM.

The examination of the body was made nine hours after death. The countenance still bore traces of the purple hue, and of the anxiety which had characterized it, and which bore resemblance to that of one suffering under tetanic spasm. The body was little, if at all, emaciated; the limbs were very rigid, and the diseased arm was undergoing decomposition more markedly than the other. The head was examined carefully, but no appearance presented itself, either in the brain or its membranes,

which could be held to be the result of the previous disorder. The quantity of fluid in the ventricles was minute. In the chest some firm adhesions existed between the pleurae on both sides, but the heart and lungs were sound; and the abdominal viscera all were apparently uninjured.

The limb was slightly enlarged, and livid; and the wound, where all the mischief had arisen, was small, but its orifice was patent, and rather sloughy. The cephalic vein was thickened, hard, and impervious in parts, for a considerable distance above and below; the cellular substance in its course was condensed, and so intimate were the adhesions between it and the vein, that it was not possible, by careful dissection, to remove it entire. The vein had, for an extent of about four inches from the wound, a ligamentous appearance; its cavity was but partially obliterated, for portions of it, when cut into, were pervious; the inner membrane was not particularly red; a small purulent deposit was found close to the vein, near the wrist, and one or two similar ones in the course of the vein in the arm. The subcutaneous veins in the forearm were thickened.

The post-mortem examination bore out the decision of Dr. Baillie, "that some diseases consist only in morbid actions, but do not produce any change in the structure of parts: these do not admit of anatomical inquiry after death." The cause of the intense constitutional derangement ending in death, had left no trace; for the alteration of structure in the arm was neither of a kind, nor to an extent, to account for the consequences which had resulted from its influence over the system. It may be added, too, that the limb was never so much affected as, apart from the sympathy of the whole, to cause uneasiness. Redness, swelling, and tension, are often found greater where danger to life is never apprehended; and the pain was so trifling at times (and during the height of the disorder), that it was necessary to caution the patient against raising the arm from the pillow on which it lay, and assisting himself in the application of the poultices and fomentations.

The cause of this disorder was, it may be assumed, inflammation of, and consequent change of structure in, the vein; and that that inflammation acted either by continuity of surface upon the right

side of the heart, and so indirectly, or else by an absorption of the fluids, the products of this augmented action, directly, upon the brain; which was the source of all the symptoms.

The brain was disturbed, as was the ganglionic system (so to express myself) from the commencement. Headache, rigors, purple hue of countenance, anxiety, jactitation, vomiting, dysuria, swollen tense abdomen, and, above all, hurried action of the heart and circulation.

In saying that the brain was disturbed we come far short of the knowledge which is desirable; for we know neither in what that disturbance consisted, nor how the disorder was communicated through the system: we witnessed the phenomena, but these left no tangible signs.

There was not one trace certainly of inflammation. It would not have been possible to have distinguished the brain or the thoracic viscera of this subject, from one dead under other circumstances; and pathology seems to offer therefore (save what may be gathered and inferred from the phenomena during life) but little solid information.

It has been conjectured, I am aware, that the pus which is found very universally in small dépôts in the course of the vein in these unhappy instances, is absorbed, and so becoming a poison, acts deleteriously upon the brain. This opinion is probable; for we know the sudden and deadening influence which results from the introduction of air, or other fluids, into the vascular system.

Pus was not found, however, in the course of the examination, in any vessel, not even in those portions of the diseased vein, which were still partially pervious. But may not the mucous fluid* which lubricates the inner tunic of the venous system (acting probably as a sheath from the contact of the blood) have been augmented, or deteriorated, or altogether stopped? or, may it not have been changed in quality? may not some change, or changes, so produced, have acted deleteriously upon the brain?

Pathology here, as unhappily in many other affections, sheds no light on the nature of the ailment; it shews only

what it was not; and if any good arise from narratives like this, it results from making apparent the value of precaution, and the necessity for watching the first signs of danger. Had the man complained when uneasiness was first felt, or had due inquiry been made, that local injury might have been prevented, which, once it had exerted its influence upon the constitution, became the source of suffering and of death.

With respect to the treatment, it was directed in great measure according to the symptoms. When the patient was first seen at the Military Hospital, the disease was still apparently local and mild: simple means, with confinement to bed, were used, but symptoms of specific disorder soon manifested themselves, and the indication seemed to be that the system should be supported and quieted,—should be borne through, if I may so say, a given period; when the morbid influence having ceased, and its consequences having subsided, the body would have been left liable only to its wonted agencies. This period of calm, or cessation of disease, unhappily (although suffering was mitigated), was not attained: disease seemed to have,—without relation to the local injury, the parent of all the ill,—entire possession of the frame; and it continued with partial vicissitudes and modifications, but little, if at all influenced by the means employed, until the 10th day after admission, when life was exhausted.

The features of the case were so forbidding all through, that prognosis from the moment that the constitution participated in the disorder, was unfavourable: yet still hope was not finally abandoned, until the state of coma, livid countenance, and stertorous breathing, seemed to indicate a change of structure in the brain which precluded all possibility of recovery.

July 1832.

A Case of Phlebitis, with organic mischief in the Chest, which terminated favourably.

Private Henry McArdle, ætat. 22, 29th regiment, an athletic young man, of sanguine temperament, was admitted into the Regimental Hospital, Port Louis, on the 10th of March, 1834, with an irritable sore on the glans penis, for which he was bled on the 11th, and placed

* "En dedans, la membrane interne du système vasculaire est sans cesse humectée d'un fluide muqueux, dont les sources sont encore ignorées, et qui la garantit de l'impression du sang avec lequel elle est en contact." —Bichat, *Traité des Membranes*.

upon the strict antiphlogistic plan of treatment: he was confined to bed, and cold evaporating lotions were locally applied. On the 25th, the sores being stationary, with a hardened base, he was again bled from the same place, namely, the median basilic vein of the right arm, the former puncture having healed by the first intention. On the 26th, about 9 o'clock, A.M. he was seized with severe headache, and other symptoms of ardent fever; and at 2, P.M. the pulse was 136, and vibrating; headache intense; skin burning hot; thirst urgent; and countenance anxious. When questioned as to the state of his arm, he said it felt stiff and painful; and, on examination, it was found that it was somewhat swollen and tense from the seat of the puncture, ascending upwards in the direction of the vein, and that the lips of the wound made by the lancet were patent, which he attributed to the bandage having been put on too tight by one of the patients the preceding night, as it had come off accidentally.

A large emollient poultice was applied to the arm; a calomel and colocynth pill administered; and at 6, P.M. the febrile symptoms were found to have abated, and the arm was less painful. The medicine not having operated, pulv. jalap. c. ʒss. was prescribed, and the poultice renewed. At 8, P.M. the medicine had operated once, and he felt easier; pulse 112, soft; cooler skin; violent thirst.

Enema purgans. R Calomel. gr. ij.; Pulv. Antimon. gr. iij. M. ʒiis hor. sumend.; et app. Cataplasma. emoll. 3tia quaq. hora.

27th.—He slept little during the night from the pain of his arm, and there is considerable tension and swelling extending from the puncture upwards in the line of the vein, and there are several red lines perceptible in the integuments, running in the direction of the axilla; pulse 94; skin hot; thirst urgent; countenance anxious; one scanty motion in the night.

Olei Ricini, ʒj. statim sum. Contin. cataplasma. emoll. applic. brachio.

6, P.M.—He was seized at 3, P.M. with an exacerbation of fever, which still continues; respiration laborious, and countenance anxious; pulse 118, vibrating; the arm is very tense and painful.

App. Hirud. sex brachio, et postea contin. catap. emolliens.

R Calomel. gr. iv.; Ext. Opii. gr. ½. M. fiat Pil. 3tiis hor. sumend.

8, P.M.—He feels easier, but he is very restless, and has no inclination to sleep; skin hot.

R Tinct. Opii, gtt. xlv.; Vini Antim. gtt. xxxv.; Aquæ Menth. Pip. ʒi. M. s. s.

28th.—He slept a good deal during the night. There is less febrile disturbance, and the arm is less painful this morning. The leeches were not applied, as none could be procured in the town. Pulse 92, soft; skin hot; thirst urgent; bowels slow.

R Calomel. gr. v.; Ext. Colocynth. c. gr. ʒjss. Contin. cataplasma. emoll. Imperial drink, ad libitum.

6, P.M.—The medicine has operated thrice; fever abated; and arm little painful.

7, P.M.—Seized with acute pain in the right side of the chest, impeding respiration, which is hurried; and he has great difficulty in swallowing; apparently from spasm in the muscles of deglutition. Pulse 112, small and vibrating; countenance anxious; thirst very urgent; skin hot.

R Tinct. Opii, gtt. xlv.; Spirit. Æther. Nit. ʒss.; Vini Antimonialis, gtt. xxv. M. s. s.

29th.—He slept well during the night; pain of side less; he can now swallow without any difficulty; and the arm is free from pain, the swelling and tension is more circumscribed, and the red lines which extended towards the axilla have disappeared. Pulse 92; skin cooler, and countenance less anxious; thirst urgent, and bad taste; tongue coated; bowels open.

R Mist. Camph. Liq. Ammon. Acetat. sing. ʒiv. Sumat ʒjss. 3tia quaq. hora. Contin. catapl. emoll. brachio.

1, A.M.—Pain in side more acute; pulse 94, firm; skin hot; thirst urgent.

Fiat statim venesectio.

R Calomel. gr. iij.; Ext. Opii, gr. ½. M. 3tiis horis sumend.

6, P.M.—Blood (lb. iss.) buffy and cupped. He does not complain of any pain; pulse 82, soft; skin cool; little thirst; bowels open.

30th.—He slept well during the night, and he feels much better to day; mouth sore, with slight pyralism. The arm is free from pain; the swelling is cir-

cumscribed, and more elevated in the centre, which gives a sensation of indistinct fluctuation to the touch.

Habeat Garg. Alumin. Contin. catapl. emolliens.

31st.—Pulse 84, soft; arm free from pain, little tense, and the swelling is subsiding. He has still pain in the side on making any exertion; mouth continues sore; skin rather hot.

9th.—He had urgent cough, with dyspnoea, during the night; expectora-

tion copious and muco-purulent; perspires much; and he is weak and emaciated; pulse 92, soft; bowels regular.

Contin. Mist. ut heri.

10th.—Cough and expectoration continue; pulse 84, soft; bowels open.

Contin. Mist.

11th.—He slept better, and had less cough during the night; pulse 60, irregular, and intermitting; perspired much.

Omitt. Tinct. Digitalis. Contin. alia.

12th.—He continues to improve; pulse 42, intermitting; he has some appetite; bowels slow.

Pil. Aloes et Myrrh. et Ext. Colocyn. c. ut antea sumend.

13th.—He slept well during the night, and has little cough or expectoration; pulse 40, irregular, and intermitting; bowels open.

Contin. ut heri.

From this period he progressively improved, the constitution having continued under the influence of digitalis until a few days before he was discharged from the hospital, on the 13th May, in good health.

The favourable termination of this case may, I think, be mainly attributed to the restorative powers of a strong and healthy constitution; and, in this view, the treatment was conducted,—to restrain and moderate the constitutional disturbance which was set up, for the purpose of arresting the local malady, that had arisen from some undefined cause. For the secondary affection of the chest, induced (as it has been generally supposed in similar instances) by the inexplicable agency of the nervous system, medicines of the soothing and antispasmodic class were prescribed; and this affection having terminated in organic disease, moderate bloodletting was employed, and digitalis was given in large and frequently-repeated doses, so as to bring the constitution under its influence rapidly, which, having been accomplished, the most urgent symptoms began to subside, and progressive amendment took place; the body, which had been much wasted, recovered its wonted plumpness; the general strength was restored; the patient was discharged to duty; and he has since continued in the enjoyment of robust health. It may be worthy of observation that the circu-

lation continued an unusual length of time under the influence of medicine, and with the happiest effects apparently, the pulse never exceeding 46, until within a few days before the patient was discharged.

Port Louis, Mauritius,

REPORT OF CASES
OF
CONVULSIONS OCCURRING IN
PUERPERAL WOMEN.

By FLEETWOOD CHURCHILL, M.D.

Licentiate of the King and Queen's College of Physicians in Ireland; Physician to the Wellesley Lying-in Institution; and Lecturer on Midwifery in the Medico-Chirurgical School, Digges-Street, Dublin.

To the Editor of the Medical Gazette.

SIR,

If the following cases of puerperal convulsions appear to possess sufficient interest, you will oblige me by inserting them in your useful journal. They occurred (with one exception), in the practice of the Wellesley Lying-in Institution, under the care of Dr. Maunsell and myself; and are related as they were entered in the case-book.

I have the honour to be, sir,

Your obedient servant,

F. CHURCHILL.

104, Stephen's-Green, Dublin,
Oct. 8, 1834.

CASE I.—*Hysteric Convulsions.*

On the evening of February 2d (Sunday), I was sent for to see Mrs. —, in Camden-Street. I found her unable to speak, but evidently hearing me when I spoke to her, as she attempted to answer, and could not. She breathed naturally, and her pulse was calm and soft. She was six months gone in pregnancy. On placing my hand on the lower part of the abdomen, I could feel the uterus contracting; and at each contraction she tossed herself about on the bed. Except at these times, I saw no convulsive efforts. The women in the room spoke of the convulsions as occurring occasionally. No frothing at the mouth; no distortion of the face, or biting of the tongue; head cool; pupils contracted on the approach of light; no hæmor-

rhage; skin of a natural colour and heat.

The labour went on, and I delivered her of a female fœtus, about six months old. Hæmorrhage neither accompanied nor followed the delivery. In due course of time the placenta was expelled, and the uterine firmly contracted.

From the absence of epileptic or apoplectic symptoms, I was led to believe this one of those cases described by Burns, Dewees, and others, as hysteric convulsions; I therefore ordered

Træ. Opil. grt. xx.; Træ. Asafæt. ʒi.;
Aq. ʒi.

to be given directly; and enjoined quiet.

Upon making further minute inquiry as to her previous state, I found that she had been complaining for the last fortnight of feverishness, but I could make out no local disorder. The morning of the day on which I saw her she complained of thirst, and drank half a pint of mulled porter. She spoke as usual, but seemed heavy. Soon after, her husband left her; and on his return she could not speak, and had several convulsions.

I called early the next morning, and found that she remained much in the state I left her the night before, save that she had fewer convulsions, and seemed more sleepy, until seven A.M., when she died. The skin after death assumed a jaundiced hue. I could not obtain permission to inspect the body.

REMARKS.—This case appeared to me interesting, even although the details are so slight. It establishes, I think, the existence of a species of convulsion distinct from the epileptic or apoplectic, and yet as grave in its results. Every symptom, or nearly so, which marks those species, was wanting, except the inability to speak: there appeared no greater lesion than the disturbance of an hysteric paroxysm; the head was cool; there was no foaming at the mouth; no distortion of the features; no stertorous breathing; a quiet pulse, and cool skin; and yet, without any addition to these symptoms, she died. How can her death be explained? I profess myself utterly in the dark.

CASE II.—*Epileptic Convulsions.*

On Monday evening, February 11, 1833, I was requested by a pupil of

the Dispensary to see a poor woman in Ship-Street. The whole of the preceding night she has complained of great pain in the head. She has received no blow or injury; is a sober, quiet woman, and is at her full time. On visiting her this morning, the pupil found her headache continuing, with turgidity of the veins of the neck, and a quick strong pulse. She was perfectly sensible, but had had several convulsions. He bled her to 16 oz., which had no effect, however, upon the paroxysms.

I found her nearly insensible, incapable of answering any questions, but constantly crying out "Oh, my head!" The convulsions recurred every three-quarters of an hour: during the paroxysm, the body and limbs were strongly convulsed; she frothed at the mouth; her features were distorted, and her hands forcibly clasped. After a few minutes this subsided, and she breathed heavily and rapidly, succeeded by long-drawn inspirations, gradually becoming more natural. She slept the whole time until the next fit: pulse quick and firm, though not full. Shortly after my arrival, the uterus was observed to contract for the first time. The bleeding was repeated, the head shaved, and a cold lotion applied to it.

On making a vaginal examination, the head of the child could be felt at the os uteri, through the membranes. As the parts were dilatable, I ruptured the membranes, and the waters being discharged, the pains became regular, though not very quick. The fits continued, and in about three hours a dead child and the placenta were expelled without hæmorrhage. An opiate enema was administered, and a blister applied to the back of the neck. The surface became cooler, and the pulse weaker.

Feb. 12th.—Fits continued all last night, with intervals of half an hour or an hour. She neither spoke nor appeared sensible; pulse quick and strong; surface and head warm. I opened the temporal artery, and took away 20 oz. of blood: the pulse became weak and her face pale, but she evinced no sensibility. Towards night the violence of the convulsions diminished somewhat, and at one o'clock in the morning they ceased entirely. In the morning (Feb. 13th), she took some tea, and became sensible, recognizing some of her attendants. A cathartic clyster was given, and purgative powders, which operated well.

Delirium came on towards evening, and continued for some days, and then gradually subsided. She remembered events up to the period of her seizure, but nothing afterwards.

CASE III.—*Epileptic Convulsions after Delivery.*

Sept. 19th, 1833.—Margaret Dalton, æt. 23, of an apparently broken-down constitution and phlegmatic temperament, subject to slight hysterical paroxysms, and, during her pregnancy, to œdema of the lower extremities, which extended even up to the parietes of the abdomen, was safely delivered of her first child, a healthy daughter, after a natural labour of twelve hours duration, in the course of which nothing occurred which could lead us to expect the dreadful attack she was about to suffer. Her bowels had been well freed by medicine and injections both before and during the course of the labour. Seven hours after the child was born, she was suddenly seized with convulsions, which were very violent, and came on at very short intervals: in one which I witnessed, her body was violently raised from the bed, and thrown backwards, like a strong paroxysm of tetanus; her hands were clenched, and she frothed at the mouth. It lasted for about two minutes, and appeared to be shortened by dashing water into the face. In the intervals of the fits, she lay in a kind of light coma, occasionally opening her eyes, and tossing herself about. Pulse very quick, and rather hard; all the while perfectly insensible. Dr. Maunsell saw her about 11 A.M., and by his directions she was bled to xxvi ., had a turpentine enema, and a bolus of calomel and jalap; her head was shaved, and cold applied to it.—Two P.M. Had one fit since last visit; coma continues; face pale; pulse 128, softer. The injection stupes to the abdomen, and a blister to the head.—Seven P.M. Continues in the same state: pulse so quick as scarcely to admit of being counted; had three fits since one P.M.; no discharge from the bowels; the abdomen, however, is soft. Repeat the enema and fomentations.

20th.—Better; bowels have been freed several times; urine scanty; pulse 155, more full and soft; pupils natural. She had one fit at three this morning, which was less violent than the preced-

ing ones. She is now in a sleepy state; answers yes and no, and now and again calls for drink. At one time she said she was very weak. Ordered

Cal. gr. ij.; P. Zing. gr. iij.; ft. bolus, ter in die sum.

Evening, much better; recognizes her friends. In consequence of her having taken, without orders, a senna draught after the bolus, she was purged violently during the day; urine much increased in quantity; pulse 120; tongue clean and moist; still complains of thirst, and asks for drink. Ordered

A blister to the neck and a foetid enema.

From this time she recovered rapidly. She retained no recollection of her labour, of her having engaged a midwife, or indeed of any event for three or four days before her confinement.

CASE IV.—*Abortion in the Sixth Month, with Epileptic Convulsions.*

Mary Doyle, a strong-looking woman, with thick, short neck, and of a leucophlegmatic temperament, on the morning of the 10th of December, 1833, at three o'clock A.M., was seized with pain in the epigastric region, which increasing, she sent for medical aid. She was visited at half-past four o'clock A.M., and found tossing herself about in bed, endeavouring, by change of position, to procure herself a moment's ease. Her pulse was quick and hard; tongue white. She complained that her heart would burst; and on examining, I found considerable tenderness over the epigastrium. She had retched frequently, but had thrown up nothing except thick mucus. She had no labour pains. She was somewhat more than five months gone with child; has had six children, of whom the first is living, but the last five she has aborted at nearly the same period of pregnancy (the sixth month): she had had convulsions in her last labour but one.

On examining per vaginam, there was found no dilatations of either the os uteri or external parts. A vein was opened in her arm, and about \mathfrak{xxv} . of blood abstracted; and having ordered fomentations to her epigastrium, together with a few drops of laudanum, she was left, the pain very little mitigated. At nine A.M. she was visited, and found quite insensible; breathing stertorous;

pupils widely dilated; eye-lids half closed, and iris insensible to the stimulus of light; pulse quick and hard. The fomentations had afforded her relief for a short time; but about half-past six she had been seized with a fit, which had recurred at intervals of half an hour. She gradually recovered from insensibility, so as to answer when loudly spoken to, and was quite conscious of an examination, which it was thought proper to make, in order to ascertain if labour had made any progress, but the parts were found precisely in the same condition as before. In half an hour she had another paroxysm. Seeing, therefore, the difficulty of the case, Dr. Maunsell was sent for at 10 o'clock A.M. Dr. M., on his arrival, ordered \mathfrak{xx} . more blood to be abstracted, a turpentine enema administered, head shaved, and cold applied, as also affusion of cold water to the face during the presence of each paroxysm. A bolus of cal. and jalap ordered at 11 A.M. Three quarters of an hour between each paroxysm. No interval of sensibility. The bolus had been introduced into her mouth, but only part had been swallowed, the rest having dribbled away with the saliva; enema had operated but imperfectly. No appearance of labour. Ordered by Dr. Maunsell

Ant. Tart. gr. iv.; Aq. \mathfrak{viiij} . sumat. \mathfrak{zj} . 2da quaq. horâ.

Three P.M.—Paroxysm more frequent; pulse very quick, and irregular; lies still insensible; one pupil dilated, the other contracted; breathing stertorous. Had vomiting after each dose of tart. emet., but was now unable to swallow any thing. Ordered another turpentine enema, which was rejected almost immediately, little altered.—Four o'clock P.M. Drs. Maunsell and Darley saw the patient. No amelioration in the symptoms; paroxysms rather more severe; pulse 120, small, and occasionally irregular. \mathfrak{xx} . of blood were abstracted, which not suspending the convulsions, and her pulse not warranting the abstraction of more, Drs. M. and D. having examined per vaginam, and found no dilatation of the parts, decided on rupturing the membranes, which was done by Dr. Maunsell, and exit given to the waters, which were of a somewhat darker colour than usual. A small quantity of very turbid and chocolate-coloured urine was also drawn off. Ordered

A blister to the neck; Hydr. Submur.
gr. v.

which was introduced upon the tongue, but could not be got down.—Nine o'clock. Drs. M. and D. saw her again. Lies in the same state of insensibility: pulse very quick and feeble; had had several paroxysms since. After some time, she appeared about having another paroxysm, which seemed to be averted by a plentiful dashing of cold water on the face (to the stimulus of which she was for the first time sensible); at least its character seemed so much softened, as hardly to deserve the name of convulsion. This was quickly succeeded by pain of a peculiar character: she now tossed about her arms, alternately extended and flexed her legs; her face being at the same time expressive of agony. The parts were now found to be well dilated, and labour considerably advanced; and shortly after a female fœtus was expelled (twenty minutes after nine o'clock). No pulsation in the funis. The placenta was felt in the vagina, from which it was extracted by Dr. Maunsell in twenty minutes. When leaving her, she lay tranquil, and seemed asleep; no opiate was therefore thought necessary.

December 11th; half-past ten o'clock A.M.—Had had no paroxysm since three A.M., but had three previously; the last unusually severe, both in duration and violence. Still remains insensible; respiration 48 in a minute, and laboring; pulse 160, weak, and fluttering.—Three P.M. Breathing more laborious; pulse not to be felt; death mucous râle; spasmodic attempts occasionally at extending the arms; eye-lids semi-closed, &c. Some purging medicine had been ordered since morning, but it could not be swallowed. She lingered in this condition for an hour, when she expired, thirty-six hours after first attack. No examination could be obtained.

REMARKS.—The foregoing three cases present well-marked symptoms of an epileptic character. In the first only of these were there any premonitory symptoms; and in one only was there any decided effects from the remedies employed.

The termination of case 2 in mania was very remarkable. I think I have met with but one or two similar cases in writers on this subject. The delirium continued some time; and once she

made a violent attack on her attendants: during this time her appetite was good, and her bodily health improved.

None of the patients could recollect being attacked with the disease.

CASE V.—*Apoplectic Convulsions.*

For the following case I am indebted to my friend, Dr. Aston, of the Cork-Street Fever Hospital.

Catherine Costello, aged 18 years nine months, of low stature and corpulent figure, complained first of severe headache on Wednesday, 2d January, 1833. The pain was more violent than any of the kind she had ever experienced. Sickness of stomach set in nearly at the same time, and she continued throwing up green bilious matter at intervals during the entire day: the bowels were confined for four days; the face and upper extremities were very much swelled, which commenced two days before, and continued gradually to increase as the headache became more intense. She wanted about seven weeks to complete the usual period of utero-gestation. I was sent for in the evening: she was walking about the room, but suffering most acutely; the face was swelled to such a degree as almost to hide the eyes, and her speech was somewhat thick. The motion of the child had not been felt all day. As she had an objection to bleeding, I omitted it for the present, and directed some opening medicine, to relieve the bowels; and having given the requisite instructions, I left her; but in a few hours after, her husband came for me in all haste, requesting my immediate attendance, as she had had a fit, and appeared to be in a dying state. Upon further inquiry, I was told that the pain in the head got much worse, when suddenly the eyes became fixed, the face distorted, convulsive motions ensued, and ended with stertor, which must have been of short continuance, as no such symptoms existed when I visited her a short time afterwards, although she was unconscious of any thing that happened until after venesection, which I immediately performed, to the extent of 18 or 19oz., from which she experienced almost instantaneous relief. The heat of skin was much greater than natural; thirst extremely urgent; pulse pretty frequent, but inclined to hardness: after venesection, it became quicker; shortly after, slower and softer, until it gradually

came down to the natural standard. The bleeding was continued until decided relief was expressed. As she was now comparatively free from pain, and disposed to rest, I left her, after giving the necessary directions.

On the following morning she was much better; swelling of face and upper extremities much reduced; bowels freed thrice. No swelling of lower extremities has occurred at any time.

4th.—Out of bed, and walking about, nearly as well as usual. No thirst: has some appetite. Complaints of pain across the back; otherwise well; bowels were confined. Opening pills were ordered.

She was safely delivered the following day, and had no recurrence of the attack.

CASE VI.—*Apoplectic Convulsions.*

Mary —, æt. 30, was attended in her first confinement by a pupil of the Wellesley Institution, Tuesday, November 20, 1832. The labour was natural, and terminated within a moderate time. She had complained of severe headache during her labour, and seemed sleepy towards the conclusion. After asking some questions of the attendants, and then settled to sleep, some irregular twitching motions of the limbs were observed, but nothing more. Her breathing shortly became loud and heavy; and I was sent for. I found her perfectly insensible; pupils fixed and contracted; breathing stertorous; heat of head not much increased; abdomen distended with flatus; muscles perfectly flaccid; pulse firm, though not full. I instantly bled her, cut off her hair, applied cold to the head, a blister to the nape of the neck, and hot fomentations to the feet—but in vain; for without any interval of improvement, she sunk, and died during the night.

A post-mortem examination was permitted, and we found a great effusion of blood, filling both ventricles and the serum occupying the base of the skull. On further inquiry, I found that she had been seduced and betrayed, and that her situation had preyed upon her spirits, causing severe headaches, for some weeks previous to her confinement.

REMARKS.—These last two cases differ very decidedly from any of the preceding ones: both had premonitory symptoms, and in both the convulsions

assumed a milder character. Case 5 answers exactly to Abercrombie and Lallemand's description of simple apoplexy without effusion; and the treatment was as successful as in their cases. Case 6 was, in fact, apoplexy from effusion—the slight convulsive motions taking place probably at the commencement of the effusion.

Two or three observations, by way of resumé, may be permitted.

1. The cases I have related mark out pretty clearly three distinct species of puerperal convulsions, as noted by Dewees, &c.—the hysterical, epileptic, and apoplectic; all of which may prove fatal, though none are necessarily so, except the apoplectic from effusion.

2. According to authors, the two first species may prove fatal, and yet leave no pathological changes observable after death.

3. In the two first kinds, no inference can be made as to the exciting cause; of the two latter, probably the predisposing were, in case 5, the plethoric habit of body and the constipation; in case 6, continued grief; and in this the exciting cause was manifestly the interruption to the return of blood from the head during the labour pains.

4. The symptoms differ in each species: in the hysteric we find less convulsion, some twitching and tossing about, and generally sobbing, without violent contraction of limbs, contortion of face, or stridulous breathing. In the epileptic, we have, in addition to the insensibility common to all during the fit, violent convulsions, twitching of the body, frothing at the mouth, biting of the tongue, distortion of features, with stridulous breathing at the termination of each fit. In the apoplectic, the fit is milder: convulsive motions occurring at the commencement of the attack, heat of head, flushed face, stertor, contracted pupil, and flaccidity of muscles, distinguish it from the other species.

5. That our prognosis should be guarded—for although grave, yet, except in apoplexy from effusion—the case is not hopeless.

6. In the two first kinds, the removal of the child by *natural efforts* is desirable, though it would be questionable practice to have recourse to art. Except in the third form, bleeding appears of doubtful value: blisters, cold to the head, and purgatives, produced more apparent effect.

CASE OF
EXANTHEMA AND NARCOTISM,

From the External Application of Hops.

By JOHN BADHAM, M.D.

MARY BELL, æt. 14, and of a healthy habit of body, applied for advice, on the 26th of September last, for symptoms which, although on the decline, appeared to me even then of a sufficiently interesting character to deserve being detailed in my case-book; and as I have not been able to find a case of the kind recorded by any authors, English or foreign, I shall be glad to hear whether any of your correspondents have, in the course of their practice, met with a similar one. This little girl had been engaged in hop-picking for a week, during which she was in the enjoyment of perfect health.

On the morning of the 24th, there being a sharp frost at the time, her hands became chapped, and she put them into the hop-bin to warm them. Shortly after this, she began to feel a tingling or smarting sensation in the hands, as if she had been stung by nettles; and having frequent occasion to pass her hands over her forehead, to arrange her hair, the face became similarly affected. In a few hours afterwards, a distinct cuticular efflorescence appeared, accompanied with a strong disposition to sleep. When taken home, the feeling of somnolency was such as to require the constant vigilance of the family to keep her awake. Her vision was so much impaired that she could not distinguish between objects the most dissimilar; a plate of eels, for instance, appeared like mushrooms. Toward evening all efforts at rousing her attention failed, and she fell into a profound slumber. In the morning her face was covered with a deep erythema, and had swelled extensively; her eyes were quite closed by the tumefaction of the eyelids. She slept substantially through the whole of that day, but once or twice complained of pain in the forehead. Opening medicines were administered, but failed in procuring a stool. On the evening of this day the hands and face were literally covered with vesicles, some of considerable, some of lesser size, which, continuing to grow larger, at length began to burst, first in the hands, then in the face. After this a considerable

mitigation in all the symptoms took place; the face became reduced in size, and a healthy desquamation soon followed. The eyes, which had suffered from the attack, though less inflamed, were still red, on the fourth day, when she presented herself to me; and there was also an appearance of *small scales* on the face and forehead; elsewhere the desquamation was general; the erythema was dying away, but a thin ichorous discharge kept oozing from small abraded patches between the fingers. She still had headache, and appeared heavy, but was evidently convalescing without medicine: however, as her bowels were confined, I gave her saline purgatives, with the addition of a little nitre and sulphur, and ordered the hands to be dusted with some absorbent powder. These means, with the additional aid of a dose of calomel and colocyath, completed the cure which had already been commenced by nature.

The interest of this case appears to consist, first, in its appearing to prove the physiological fact of cutaneous absorption; and, secondly, because it discovers a new and hitherto unsuspected acrid principle in the hop.

Workshop, Notts,
Oct. 1834.

HYDROTHORAX AND HEART
DISEASE,
AS CONNECTED WITH
RHEUMATIC AFFECTION.

To the Editor of the Medical Gazette.
SIR,

DURING the last thirty years I have often observed that persons who, in early life, have been subject to rheumatic inflammation, have frequently, at a later period, suffered from disease of the heart, and sometimes of the pericardium, not infrequently producing hydrops pericardii; and when neglected, or not properly treated, hydrothorax and general anasarca have set in, attended by all the distressing symptoms usually connected with them. In some instances I have seen gouty inflammation produce disease of the heart, which, though little noticed during life, has yet ended in sudden death. The only symptoms complained of during life have been, perhaps, a little shortness of breathing on extra exertion, or some slight sense

of palpitation of the heart, which had been attributed to the stomach. In other instances there is more immediate pain, which is often felt in the left arm or shoulder. Where the heart alone is affected, I have seldom met with cough; but where the pericardium is primarily affected, or any of the membranes in its neighbourhood, it generally is attended with a dry tickling cough. But the greatest inconvenience is found upon increased action of walking, particularly up hill or up stairs; in which cases the pulse is generally excited. I invariably find bleeding, purging, or diuretics, as the case may require, the only effective remedies; for, in cases that I have examined after death, I have often found traces of inflammation either in the heart or pericardium, or hypertrophy of the heart, or disease of the valves, where the patient did not complain of pain in the part. In most of those cases there was a florid countenance, and generally a quick pulse, and very sharp. The intermission does not come on in general, in the younger subjects, till some disorganization or effusion takes place; but even then I have found it may be removed, by removing the cause.—I am, sir,

Your obedient servant,

WM. JONES.

Lutterworth,
October 9, 1834.

I was called to T. B., aged 67, who had been unable to lie down for nearly three weeks. I found the countenance bloated; the lips blue, or purple; the pulse intermitting every second or third beat; the legs and thighs enormously swollen; the scrotum so large that the penis was quite hidden; the abdomen very tumid, and the skin œdematous; respiration very quick and laboured. I found he had been treated generally for dropsy; that he had been a hearty man, lived freely, and had no complaint except occasional rheumatism. I immediately ordered him a brisk dose of calomel and colocynth, and gave him a dose every night, for four or five nights; had the scrotum punctured; drew off a large quantity of fluid; applied a blister to each leg, kept up brisk action of the bowels, and excited the action of the kidneys by calomel, digitalis, and squills; and kept down the febrile action of the system by neutral salines. In six or seven days he could lie down; the whole of

the water in the chest was absorbed in three weeks, and the pulse became regular; and in a month's time, the only symptoms he had were debility, for which he took, for a short time, the infus. gent. comp., with a little sulph. magnesia for a short time, when he was quite well. About ten years afterwards I saw him in perfect health, having had no return of his disease.

I was called to a patient, æt. 46, who had a very large family; had been ill, she informed me, several months. She had ascites, with great anasarca of the legs and thighs; pulse intermitting, and very short of breath; tongue thickly furred; great thirst; and unable to lie down. I put her upon the antiphlogistic plan, with neutral salines and diuretics, keeping up the action of the kidneys with mercurials occasionally; by which the whole of the water was absorbed. The appetite returned, and she became convalescent after a few weeks. From exposure to cold and wet, she was attacked with acute inflammation of the liver, and in the onset refused to be bled. Being already greatly debilitated, her disease very soon terminated fatally.

I was called to a young person, æt. 22, who appeared to be dying from hydrothorax and excessive anasarca of the lower extremities. Upon inquiry, I found she had been subject to rheumatic pain in her limbs. The lips were purple, the countenance bloated, and breathing very difficult; the pulse very irregular. She had not been able to lie down for a fortnight, as I was informed. I blistered her legs, brought the bowels into brisk action, excited the kidneys, as in the former cases; and by removing the fever from the system the debility left her, and she has been now for two years quite well, without any return.

EXTRACTS

FROM A

JOURNAL OF NATURAL HISTORY;

Kept during a Voyage from England to New South Wales, and on the return to England, by way of Batavia, Pedir Coast, Singapore, &c.

By GEORGE BENNETT, Esq.

On the 20th of February, in latitude 19 deg. 21 min. S., and longitude 1 deg.

47 min. W., I had no success with the towing-net until about 9 P.M.; when I found in it a solitary specimen of a molluscous animal, resembling *Biphora*, beautifully transparent, almost octangular, with prettily-marked streaks at the divisions of each angle. It was of a firm nature, and could be handled without sustaining any injury.

At 10 P.M. I found a solitary specimen of *Salpa*, perfectly vitreous; which, on my placing it in a tumbler of water in my cabin (which was dark at the time), after removing it from the towing-net, it gave out, for a short time, a very beautiful phosphoric light; which proved to me, by the wide diffusion of the luminosity, how capable the animal was of extending its light to a wide distance. The luminosity subsided as rapidly as it had been given out; on regarding the animal at the time, phosphoric matter could be seen exuding from every portion of the transparent body of the animal, which gradually diminished until the whole of the animal was concealed in the surrounding darkness. No luminosity was voluntarily emitted by the animal after the first effort, and even that I attribute more to the violence with which I probably plunged the animal in the water than to any voluntary power; for it never renewed the luminous powers except when disturbed by the finger, when it would display a faint luminosity of very brief duration, and dying soon after, all the phosphorescence disappeared.

February 21st, latitude 18 deg. 13 min. S., and longitude 2 deg. 43 min. W. In the evening a dolphin (*Coryphæna*, Cuvier) was caught, nearly two feet in length; the dorsal and other fins were of a fine purple colour; body silvery on the sides and abdomen, giving out a variety of tints during its expiring moments; the back and upper portion of the sides of a bluish colour, with yellowish spots. This fish being commonly known by the name of the "dolphin," is much confused with one of the *Cetacea* tribe,—the *Delphinus delphis*, or dolphin of the ancients; a species of the porpoise, which very much differs from the beautifully tinted *Coryphæna*. It was the *Delphinus delphis* that (according to Pliny) had an affection for man, and was fond of music; and he relates a story of one which carried a boy daily, for many years, across the arm of the sea from Baia to Puteoli, to

school. The dolphin and porpoise, when seen sporting in the water, is supposed to indicate a storm; but facts do not, in too many instances, accord with the assertion, to render it worthy of credit. On inspecting the stomach, I found it to contain only a few specimens of very small flying-fish, about two inches in length; the heart pulsated, without being artificially excited, for upwards of half an hour after its removal from the fish, which was done very soon after it had been taken from the water.

My only success with the towing-net was at 9 P.M. when I captured only a solitary but very fine and perfect specimen of *Alima hyalina*.

February 27th, thermometer from 76 deg. to 79 deg.; in latitude 14 deg. 24 min. S., longitude 8 deg. 5 min. W. At 8 P.M. I captured, in my towing-net, two small specimens of flying-fish; one measuring two inches, and the other two inches and a half in length.

There was also in the net several specimens of *Hyalæa dentata*, and a small fish resembling the gar pike.

About 10 P.M., on hauling in the net, I remarked a brilliant phosphoric light appearing through the meshes, from which I immediately supposed I had captured some *Pyrosoma*; but I was not a little surprised at finding the luminosity to proceed from a small shark, which was alive and alone a prisoner in the net. On placing it in the dark, when in the water, it would re-assume the beautiful phosphorescent light. I kept it in water, and it swam about for some time, but on the following morning it was found dead. On examining it on the day subsequent to its capture, the body was found to be entirely black, with the bases of the fins also of that colour, and the upper part white and transparent; it measured seven inches in length; eyes sea-green. Although the abdomen was of quite a black colour, it alone gave out a phosphoric light in the dark. I preserved it in spirits, and on taking it out again for another examination, it left, on being handled, a quantity of black colouring matter, resembling the pigmentum nigrum, about the fingers.

On the 1st of March, thermometer 77 to 80, in latitude 12 deg. 15 min. south, and longitude 10 deg. 15 min. west, at 8 P.M., the towing net captured several fine specimens of *Hyalæa dentata*, and two species of the *Medusa* genus; one

very prettily spotted with dark-red spots.

On the 2d, thermometer 77 to 81, in latitude 10 deg. 53 min. south, longitude 11 deg. 20 min. west, after dark, there was occasionally seen an extensive phosphoric light in the water, visible first at one place, then at another; it evidently proceeded from a large fish swimming about. It is seldom, however, that I had before observed luminous properties made visible in the water by these fish, many of which evidently seem endowed with luminous powers, as in the instance of the small shark before caught in the towing net; but that it is not invariably the case is evident, from having often before seen fish of different kinds swimming about, which did not give out any phosphoric light after dark. Many would say that the luminosity may have proceeded, not from the fish, but from its passing through the luminous water. Although I am perfectly aware that such an occurrence often takes place, yet in this instance there was no luminous track left by the fish in its progress, but only when it came on the surface at certain periods; and on any heavy substance falling in the water this evening, there was no phosphoric light given out by the collision; nor was there any light produced by the progress of the ship through the water, in her wake, or by the breaking of the waves; so that the luminosity must have alone, in this instance, been resident in the fish.

March 3d, in latitude 9 deg. 13 min. south, longitude 12 deg. 40 min. west, at 8 p.m., I captured by the towing net two specimens of *Eroctus*; one measuring two and a half, and the other three inches in length; together with a broad fish, two and a half inches in length, of a greenish blue over the back; abdomen and sides silvery.

There were also several large *Medusæ* (entangling many crustaceous animals), luminous, and of a pinkish or rose colour.

At 9 p.m. the net was drawn up nearly half-full of the very luminous mollusca, and the phosphoric matter discharged from them covered the deck, hands, and every thing with which it came in contact. There were occasional very luminous flashes seen on looking over the sides of the vessel, which there can be no doubt proceeded from these animals.

They are of the *Acalepha* class, and probably the *Pelagia* genus of Cuvier, *Diauca* of Lamarck; they were captured in the net of various sizes, some of them having some crustacea entangled in their tentaculae, and which probably serves them with food. The orbicular body was of a very delicate rose colour, and the arms were speckled with minute dots of a reddish-brown colour; they emitted a brilliant phosphoric light; and either when touched, or laid on the deck in the dark, bedewed every thing with a quantity of phosphorescent matter.

March 4th, thermometer 80 to 83, after dark (being in latitude 8 deg. 50 min. south, longitude 14 deg. 56 min. west), flashes of phosphoric light were seen close to the ship. A pale light was at first given out, which diffused itself for some distance around, and as gradually subsided; this by aid of the towing net was produced; it was found by mollusca of the *Medusa* genus, of a delicate rose colour, similar to those captured last night, whose phosphorescence, emitted both by pressure or disturbance of any kind, was very extensive, and while the animal survived was often voluntarily emitted, when it was seen to be diffused, as in the *Pyrosoma*, *Salpa*, &c. over the whole of the body of the animal, varying in colour from light blue to green, and the usual pallid light of phosphorus.

March 5th; latitude 7 deg. south, longitude 15 deg. 37 min. west.—This evening the towing net only captured two specimens of *Smerdis armata*. There was none of the phosphoric light emitted from the ocean, as on the two preceding nights, and consequently no luminous animals were captured.

March 6th; latitude 5 deg. 46 min. south, longitude 16 deg. 45 min. west.—At 5 p.m. I captured a small but excellent specimen of what I suppose a species of the *Physosopora* genus of Peron, class *Acalepha*. The bladder was perfectly transparent and colourless; the lobular and other appendages were of a reddish purple colour.

There was also a specimen of *Janthina*, without the soft parts. The shell differed from the one before caught, in being partially white above, and the other parts being of the usual violet colour.

At 8 p.m. a large quantity of *Smerdis*

armata, *Phyllosoma commune*, a small specimen of *Exocetus*, and some luminous *Salpa*, were captured.

At 9 p.m. the net procured me large quantities of *Smerdis communis* and *armata*, together with several small specimens of *Phyllosoma commune* and *clavicorne* mingled with them. The masses of these crustacea in the net, and their beautiful transparent crystalline appearance, certainly looked, as was remarked at the time, "as if they had been insects suddenly changed into crystals."

The range of the various *mollusca* and *crustacea* animals is certainly curious; and they seem to travel in large groups, judging from the immense quantity caught at one period in the net, and perhaps not even a solitary specimen on the evening following. The luminous *Medusæ* have passed, and now large quantities of the *Smerdis* are captured.

March 7th; latitude 4 deg. 43 min. south; longitude 17 deg. 37 min. west. —I did not capture a single specimen with the net during the day; but at 8 p.m. I procured some small specimens of *Exocetus*; some pink *Medusæ*, which occasioned some luminous appearance of the ocean after dark; and also an excellent specimen of an *Argonauta*, which seems to be the *A. tuberculosa* of Lamarck. On placing it in sea water it expanded its tentacles, but did not attach itself to the glass, or move about. I found the animal dead early on the following morning, in the glass of sea water in which I had placed it the night previous; and on moving the shell the soft parts fell out. After the animal was out of the shell, a cluster of ova was seen attached to the involuted part of the shell, somewhat similar, but in the recent state more beautifully shewn, than in the engraving of apparently a similar specimen by Sir E. Home, in the Appendix to Tuckey's Narrative of the Congo Expedition. On placing the shell in spirits, the cluster of ova floated out like a diminutive plant, of a pure white colour, presenting a very elegant appearance. After being preserved a day in spirit, much of its beautiful appearance was lost. The body of the animal was of a dark reddish colour (which colour was also given to the upper part of the shell, either naturally, or imparted to it by the animal,

the remainder being of a dirty white), with minute purplish dots, and the arms were also speckled underneath of a similar colour; the suckers were white; the diameter of the shell was half an inch.

These cephalopodous animals are not, and I consider correctly, regarded as the true inhabitant of the shell, but merely a parasitical inhabitant; and the animal not having the power of either producing or reproducing the shell, must be sufficient to decide that the one usually found is not the original inhabitant of the shell.

The animal is an *Ocythoë*, which differs "generally from the polypus in having shorter arms, with pedunculated instead of simple suckers; the superior arms too are dilated into or furnished with, a wing-like process on their interior extremities." It is mentioned in the Appendix to the Narrative of the unfortunate Congo Expedition, under Captain Tuckey, that Mr. Cranch captured several specimens of a new species of *Ocythoë*, which were swimming in a small *argonauta*, on the surface of the sea. "On the 13th of June," it is stated, "he placed two living specimens in a vessel of sea water. The animals very soon protruded their arms, and swam on and below the surface, having all the actions of the common polypus of our seas. By means of their suckers they adhered firmly to any substance with which they came in contact; and when sticking to the sides of the basin, the shell might easily be withdrawn from the animals. They had the power of completely withdrawing within the shell, and of leaving it entirely. One individual quitted its shell, and lived several hours, swimming about, and shewing no inclination to return into it; and others left the shells as he was taking them up in the net. They changed colour, like other animals of the class *Cephalopoda*; when at rest, the colour was pale flesh colour, more or less speckled with purplish; the under parts of the arms were bluish gray; the suckers whitish."

On the 8th of March, latitude 3 deg. 10 min. south, longitude 18 deg. 30 min. west, the success with the towing net in the evening, was only a solitary specimen of *Phyllosoma commune*.

March 9th; latitude 1 deg. 37 min. south, longitude 19 deg. 40 min. west.

—At 8 P.M. I captured a number of the *Phyllosoma commune*, *clavicorne*, *Hyalaea tridentata*, and several small luminous *Salpæ*, diffusing over their bodies, when placed in a glass of sea water, several phosphoric dots.

There was also one of the fragile shells of *Cleophora*, which was unfortunately broken. The animal contained in this shell seemed luminous; but as there were also a number of luminous *Salpæ* in the net at the same time, the phosphoric matter might have proceeded from them; therefore I cannot decidedly say that the animals of this beautiful and fragile shell are phosphoric.

At 9 P.M. a number of luminous *Salpæ* were taken, and a very fine specimen of the gelatinous animal allied to *Leptocephalus*, and measuring 6½ inches in length. This specimen, when first taken, was slightly inflated, which has both remained and increased since it has been placed in spirits. This confirmed what I had before conjectured to take place, from a specimen captured some time ago about the coast of Sumatra—that the animal possesses the voluntary power of inflating its body.

There were luminous scintillations, as well as occasionally flashes, about the ship during the night, proceeding from luminous *Salpæ*, and from that mollusca of the *Botryllaria* order, the *Pyrosoma Atlanticum*, one of which was captured during the night.

different diseases, both in their nature and origin.

From the records in the Colonial Office I find that variola was first introduced into this colony in 1713, by a ship from India; and that it made its first appearance in the houses of some of the inhabitants, whose cupidity had led them to purchase clothes and other goods, the property of persons who had died of the disease on board the said vessel.

The second time it occurred was in 1755, as appears by a proclamation of the Governor-in-Council, dated 21st June of that year; being introduced by a ship on her return voyage from Ceylon, and in a similar manner as in 1713, in consequence of persons purchasing the wearing apparel of those who had died of the disease during the voyage.

It is stated that the mortality on both these occasions was very great, and that the disease spread rapidly and extensively, notwithstanding the precautions taken by government, and enforced by heavy fines on any party who should deviate from the rules laid down for checking its progress; and it was not till the 11th March, 1756, that we find a proclamation ordering a general fast and thanksgiving for the cessation of small-pox in town and country.

In 1767 it again broke out in Cape Town, and, as stated in a proclamation of the Governor-in-Council, dated 5th May, it first appeared in the houses of three Europeans and a woman of colour, where the clothes of some passengers from on board a Danish vessel (the Crown Prince of Denmark), homeward bound from Ceylon, had been sent to be washed. The disease had raged on board that vessel during the voyage, and several individuals had died of it; but this information was not publicly disclosed, nor was the disease discovered to have been communicated until some days after the vessel had sailed. The same precautions were taken as in the former instances, but did not prevent the disease from spreading widely amongst the colonists.

The records of the council state that it was the unanimous opinion of the medical men, both civil and military, that the small-pox did not proceed from any indigenous or epidemic cause at this period, but from imported infection, as above stated.

The disease did not again appear in

ON VARIOLA AND VARICELLA.

By JOHN MURRAY, M.D.

Cape of Good Hope.

[Communicated by Sir JAMES McGRIGOR, Bart.]

In tracing the history of the diseases variola and varicella, as they have appeared in this colony, and with reference to my former report on this subject*, I find that variola has been known to appear here at very long intervals, when its origin could always be distinctly traced to imported contagion; while varicella exists throughout the colony, and prevails more or less every year, without ever having been known to give rise to variola; which proves, in my opinion, that they are specifically

* Vide Med. Gaz. vol. xlii. p. 438.

the colony till March 1812, although in the interim it prevailed on board different vessels in Table Bay, which were kept under strict quarantine. At this period it was introduced by a slave ship from Mozambique, which was condemned here, and the slaves landed with the contagion of small-pox existing amongst them; and I must mention a very monitory circumstance gathered from our medical records relative to this event.

The slaves on board this vessel being very unhealthy, and the commander having reported the existence of small-pox amongst them, after he had been some weeks in the Bay, a committee of medical gentlemen was ordered (on the 26th February) to examine into the nature of their sickness, and to report whether they really had small-pox amongst them or not, and whether they could be landed with safety to the community; upon which the committee reported, that "twenty individuals were found labouring under general disease of different characters, whilst four others were afflicted with the chicken poek; but in no instance does there appear to be a foundation for suspecting the existence of small-pox therein;" and therefore they recommended their debarkation.

It would be inferred from this report, without further information being given upon the subject, that the small-pox, which was communicated from this vessel, proceeded from the contagion of chicken poek; but the fact is, that the committee most unfortunately mistook the disease, and the four cases reported by it to be chicken poek were found to be cases of regular small-pox after they were landed, and of so severe a nature that two of the four died of the disease.

It appears by a statement made by the commander of the vessel, on the 26th February, the day subsequent to the examination of the committee, that small-pox had prevailed amongst the slaves on board during the voyage from Mozambique, and also after her arrival in Table Bay, and that many deaths had occurred from it on board; which information, however, he concealed in the first instance, and did not fully disclose till after another prize slave vessel had been allowed to go away on account of having had small-pox on board, and after the report of the committee; consequently it was suspected

that his statement was fictitious, and made only to deceive the government, and therefore the slaves were landed next day (28th February) without further medical inquiry being instituted; but in six days afterwards the melancholy truth was ascertained that small-pox had been introduced into the colony by them; and a proclamation was issued ordering the removal to Paarden Island of all persons supposed to be infected, and of all who had been in contact with them, into quarantine.

Between the time of the disease breaking out at this epoch, and the month of July following, when it finally subsided in the colony, 240 persons in Cape Town alone became attacked with it, nearly one-half of whom died.

The good effects of vaccination were perhaps never more conspicuously shewn than at this place during this period; for, although it was only steadily introduced eleven months previously, considering the way in which the slaves, Malays, and free blacks, which form the larger proportion of the population live together, generally from fifteen to twenty individuals in one small house, without proper ventilation, or much regard to cleanliness; and that the greater number of them had not been vaccinated till the alarm was spread of the appearance of small-pox, it is rather to be wondered at that the disease was got under so easily.

It is stated in the weekly reports made from the fiscal's office of the progress of the disease, and the result of the cases, "that vaccination was found a perfect protection against variolous contagion at this time." Very few cases occurred among the higher or middle classes, and not a single attested instance where the party had been previously vaccinated.

Among the black and coloured population this could not be so easily ascertained; but, as far as could be elicited, none who were attacked had undergone vaccination.

I would likewise notice, that I find it mentioned in the report of the 10th July, relative to two cases of elderly men, who were the last that caught the infection, "that neither of them were ever vaccinated, having been led away with the idea that they had had the natural small-pox at an early period of life;" and in the report of the following week, under date 17th July, it is stated "that

one of these had died, and that the other, who was conveyed to the small-pox hospital as having every appearance of the small-pox, was afterwards found not to be afflicted with that disease but a sort of chicken pox," which was probably the modification of small-pox now denominated varioloid disease.

Since 1812 there has been no small-pox in the colony.

In regard to varicella, I have to mention that it was in some degree epidemic this year; and in one family lately arrived from India, where it broke out, and which I attended, the youngest child, a boy of seven months old, who had neither been vaccinated nor had small-pox, became affected with it. The case was therefore observed with curiosity and interest by Dr. Smith and myself; and the progress of the symptoms, the degree of constitutional disturbance, and the appearance and course of the eruption, were found not at all to differ from those of the elder sister and other children affected, who had previously undergone the process of vaccination; in all of them the disease corresponded exactly with the description I gave of it last year in my own children.

From the way in which this disease often breaks out here I am much inclined to believe that it occasionally has a spontaneous origin, and that its cause is generated, *de novo*, from certain hitherto unknown circumstances, as it arises at times and places when it is quite impossible to trace it to its specific contagion.

In my first annual report from this place, in 1822, I noticed its sudden and simultaneous appearance and disappearance at Cape Town and on the frontiers, both amongst the military and civilians; and, although there was every reason to consider it contagious, the matter of the poeks seemed not to be infectious, as two of our medical officers inoculated several individuals with it, taken at an early stage, without communicating the disease; but the experiments could not be reckoned decisive, as it was not shown that the persons had not previously had it; and, besides, these negative experiments are not sufficient proofs of the non-existence of varicellous virus. The disease has not been confined to children, as we have had many instances of its attacking persons

after the age of puberty, and in these it has been generally very severe, yet never so much altered in character as to be in danger of being mistaken for small-pox or the varioloid disease by competent observers.

It has never been known here to give rise to variola or varioloid disease, nor to have been the result of variolous contagion; and I have not known any instance in which it affected the same person twice.

If any thing was before wanting to prove a decided difference between variola and varicella, the history of their mode of appearance here must, I think, go far to complete the evidence on this point, and to establish that they are as distinct diseases as variola and rubeola.

Cape of Good Hope,
March 1834.

REMARKABLE CASE
OF
INTROSUSCEPTION OF THE COLON
INTO THE RECTUM.

To the Editor of the Medical Gazette.

SIR,

I BEG leave to forward to you the particulars of an interesting and uncommon case of introsusception of the colon into the rectum, where the whole of that gut, with the cæcum, and about four or five inches of ileum, were found, and which, when removed from the body, had the appearance represented in the annexed drawing. The preparation is in the museum of my friend, Mr. Swan, of Tavistock-Square (to whom I am indebted for the sketch). I took it to him before the state of the parts was disturbed; and it was with difficulty (without tearing the intestine), that the colon could be drawn out of the rectum. The symptoms in this case much resembled those of strangulated hernia, faintness, with almost a loss of consciousness, depressed pulse, and constant straining, with vomiting, while nothing passed but a little bloody mucus.

The subject of the attack was a child, ten months old; and regarding it at first as a disordered state of the bowels, I administered an aperient, and after the lapse of some hours, an enema, with

a little simple cordial medicine; but these means failing to produce any mitigation of the symptoms, I inserted my finger into the rectum, and discovered a portion of the gut, about to protrude externally, round which I could easily pass my finger. This too surely indicated the nature of the case, to which no relief could be given; and the child survived only thirty hours after my being first called to it.

I am, sir,

Your obedient servant,
MATTHIAS ROWE,
Surgeon.

24, Woburn-Place, Oct. 13, 1834.

EXPERIMENTS RELATIVE TO THE SENSE OF TASTE.

To the Editor of the Medical Gazette.

SIR,

If the following account possesses any interest in your estimation, its insertion in an early number of the Gazette will oblige, sir,

Your obedient servant,
DANIEL NOBLE.

Manchester, Oct. 15, 1834.

- a, Ileum.
- b, Colon turning in.
- c, Meso-rectum.
- d, Termination of the ileum.
- e, Caecum.
- f, Cut margin of the rectum.

Mrs. Williams, about 50 years of age, 22, Pot-Street, Ancoats, Manchester, states, that some years ago she had two or three leeches applied to the left temple, near the outer canthus of the left eye, when, in a day or two afterwards, violent neuralgic pains ensued upon the left half of the face; these gradually subsided, and left almost complete amaurosis, and paralysis of sensation on the affected side of the head and face, as supplied by the branches of the fifth nerve; the function of voluntary motion remaining perfect as before. In this state she continues at the present time.

There is a peculiarity in this case to which I would particularly allude, in the fact of the sense of taste being unimpaired in the left half of the tongue, whilst its common sensibility is all but destroyed. To impressions of common tact, of pain, of the rough or the smooth, of heat or of cold, she is all but insensible; whilst to impressions of the bitter or the sweet, or any other modification of the sense of taste, she is as acutely alive on the affected as on the sound half of the tongue. For example, if she be blindfolded, and directed to protrude the tongue, and the blade of a knife be placed upon the lingual surface transversely, she feels it only on the sound side, or at least her perception on the affected side is of the most obscure description, being, as she words it, a "numb, dead feel." A portion of the mucous membrane on the affected side was lacerated with the point of a lancet, and she felt not the slightest pain—all, in her own words, being "numb and dead." The blade of a knife was introduced into hot water, and

then placed transversely upon the tongue: she had only the perception of heat on the sound side. Small portions of common salt were sprinkled upon the affected side, and similar quantities of sugar on the other: she was insensible to the fall of the particles on the affected side. In a few seconds, however, when the sapid particles had partially dissolved, she was as acutely alive to the saline taste on the affected half as to the saccharine on the other; and the sensation of taste was excited at the same distance of time from the first contact of the sapid ingredient on both sides of the tongue. These experiments were modified in a variety of ways, the woman always being blindfolded, and in ignorance of the exact procedure, or its intention; and in whatever way the trial was varied, it was obvious that whilst the common sensation of one half of the tongue was in effect annihilated, the sense of taste was unimpaired.

Does not the above case decide that taste is something more than a modification of common sensation? And if so, must it not, as in the case of smell, be dependent upon a specific nervous supply? And as a variety of facts shew clearly that the "true gustatory nerve" conveys both common and specific sensibility to the tongue, must it not be a compound nerve?

What is the function of the nerve from Meckel's ganglion, called *chorda tympani*, which joins the branch that goes to the tongue from the Gasserian ganglion?—of which nerve that distinguished neurologist, Mr. Swan, observes, "It is supposed that the chord of the tympanum does not unite with the gustatory, but passes in mere contact with this; but if a preparation that has been kept in spirits be carefully examined with a magnifying glass, and at the same time an attempt be made to disunite these nerves, it will be found that the filaments of both are intermixed, and cannot be separated without violence."

And in conclusion,—What is the function of the branches from Meckel's ganglion distributed to the soft palate?

ILLUSTRATIONS

OF THE

MALADMINISTRATION OF CERTAIN PROVINCIAL HOSPITALS;

More especially in Liverpool.

BY JAMES COLLINS, M.D.

—

I WAS obliged, from want of room, to conclude my last communication rather abruptly, with the extract from Mr. Moss's speech at the meeting of the Trustees of the Liverpool Infirmary; and I wish now to resume the subject, not from any personal or vindictive feelings, for I have none, nor to gratify any disappointed ambition or sinister object, as has been insinuated by Dr. James Johnson, in the last number of his *Medico-Chirurgical Review*, in allusion to these sketches, though at the same time he seems to adopt their sentiments. But I recur to the subject in order to put upon record some illustrations of the management of our provincial hospitals, which are not altogether without interest, and even utility, as they may enable persons unacquainted with such details to form more correct notions of the propriety or impropriety of receiving, without some other qualification than a certain number of beds, certificates of attendance on the institutions in question, or of placing them, in this respect, on terms of equality with those in London or other capitals. We are on the eve of some great change in our medical legislation, and care ought to be taken, by those who have the power, to render it as perfect and useful as possible, and to prevent the abuses which I have already detailed, and shall hereafter detail, from recurring: for it is obvious to common sense, that hospitals, even though of the same size, and having an equal number of beds, cannot afford the same advantages or instructions, (supposing the medical men to be of equal zeal, talents, and acquirements,) if the patients in the one are principally old chronic cases that are seen only once or twice a week, without any regular or detailed account of them being kept, whilst those in the other are principally acute, well selected, and prescribed for daily, with regular records of their commencement and progress entered on the books. The certificates of such hospitals ought not to be received as equivalent; to do

so is to act not in accordance with sense or the interest of the profession. The certificates of an hospital not containing fifty beds, if well managed, would and ought to be preferable to those of an hospital containing three hundred, conducted in the way alluded to; and to shew that these are not merely hypothetical or speculative cases, I must recur to the proceedings of the Liverpool Infirmary and Asylum.

I have already stated, from official documents, some very curious details in this respect, almost incredible, if not so well authenticated; for who could suppose, that in the Lunatic Asylum of such an enlightened town as this is, even so late as 1825, several patients should have been confined there for twenty or twenty-five years without its being known who they were, whence they came, who sent them, who admitted them, or any other particular about them?—that other patients in the same establishment were not seen by the medical men for five or six weeks?—that others were confined there as insane who were let out as sane by the staff-surgeon appointed by government to see them—illustrating how doctors differ? It was a curious and a novel sight to see and hear their disputes on this head; some vociferating that they were mad, while others maintained the contrary. Who could suppose that keepers would be allowed to administer medicine to the patients according to their whim or caprice? that a person confined as insane should be allowed occasionally to act as surgeon—to extract a bone from the toe of a boy, and a cupful of matter from the back of another? or that a woman should be allowed to perform now and again the office of physician?—(See the evidence of these and other similar misdeeds, in the *Liverpool Commercial Chronicle* of January, 1826.)

Though the evidence was suppressed for a long time, and a report directly contrary to it made to Mr. Secretary Peel, it was afterwards accidentally published, to the astonishment of the town, who little imagined that any set of gentlemen could be found to state, as they did, that the real grounds of complaint were confined to a few unnecessary instances of severity, and that the general management of the establishment was good. Let any man read the evidence, and contrast it with

their report, or resolutions, of the 31st of March, 1825, and then ask himself if human nature could be so disingenuous. Well might the mayor (Mr. Hollingshead) exclaim that they struck him with perfect astonishment, and that he had to accuse himself of having acted with too much courtesy and leniency. Such abuses can no longer take place: the government has since framed a new code of laws for the management of the institution in question, and I am quite satisfied, from what I know and have seen myself, that they ought to do the same for our hospitals, without interfering much with the local rights of the subscribers. A few simple general rules, included in the bill Mr. Warburton intends to bring in, or in the regulations of the Colleges of Surgeons, would suffice; rendering it imperative that the patients of all hospitals should be seen, if not every day, at least three or four times a week, by the medical men, or substitutes for them; and that no certificates should be received from any where this was not the case. This simple regulation would do more good to humanity and the progress of medicine, than all the medical cases that have been published for the last fifty years. No person who has not had local experience in these matters, can form an adequate notion of the benefits that would thence accrue to the public and the patients; and that it is not altogether so unnecessary as to many it may appear, I shall prove from the transactions of the Liverpool Infirmary. What has happened once may happen again, if we may judge of the future by the past.

At a meeting of the subscribers, convened in 1824, to take into consideration the propriety of appointing additional medical officers to the Infirmary, Mr. Freme (a wealthy and respectable merchant of this town, since dead) stated, in moving a resolution to that effect, “that the medical men did not perform their duties as the interest of that institution required; that the patients suffered much from the manner and mode of their attendance, some being there a week, others much longer, without receiving from them assistance or advice.” Mr. James Cropper, the well-known Quaker of this town, corroborated these statements, and, among other things, said, “that, in one of his visits to the Infirmary, he saw a man in the accident

ward in a most dangerous state ; and that, on asking the apothecary when this man saw his surgeon, the answer was, ' Not yet : ' he (Mr. Cropper) desired him to be attended to, and on his next visit he inquired again after this wretched patient, but, to his surprise, he was told he died the day after he (Mr. C.) had seen him, without ever having seen the surgeon under whose care he was nominally placed ; and what renders this the more criminal, is the fact that the surgeon, instead of expressing regret for not having seen him when alive, regretted only that he had not been informed when he died." Mr. Ruston, the commissioner and barrister, stated, " that in or about the previous December, a man applied for admission who required immediate relief, and that when received into the Infirmary he remained there four days before he saw his surgeon ; and that when at length he came, instead of lending his assistance to set the fractured limb, he ordered his pupil to do it the next day ; and that this man remained seven weeks in the Infirmary, and was at length removed by his friends, his ankle remaining precisely in the same state as at the time of his admission."

These and several other facts were stated, and not denied, and evidence offered to corroborate them, but in vain. The proposition of Mr. Frene was rejected, denounced as radical, amidst the indignant hisses of the majority, and a vote of thanks which was proposed by Mr. W. Currie to the medical men for their services, was carried in triumph and applause.—(See the *Liverpool Mercury* April 1824.)

To these statements I may add the fact that the medical men themselves admitted that they had done their duty as their predecessors had done ; that the practice was to see the patients on Saturday, or once a week, and those whose cases required particular attention on Tuesday. " The practice was (they say) to see all the patients on Saturdays ; and Tuesdays, those only whose cases were supposed to require particular attention. The law, however, says that they shall be seen on both days : when the revision, at Mr. Cropper's suggestion, was proposed, in 1822, this circumstance (*that is, that the patients ought to be seen twice a week*) was pointed out to us ; and since then the law has, almost without exception, been attended to." Thus

we see, by their own shewing, that they were ignorant that the laws of the institution required them to see their patients twice a week ; as if humanity and the first principles of justice did not render it imperative on them to do so. One would suppose that it ought not to have required specific injunctions, or laws, to fulfil so simple and obvious a duty ; yet so it was. Even their assertion that since 1822 the patients had been attended to and seen twice a week, is not correct ; for all the facts mentioned in the foregoing statements, relative to the Infirmary and Lunatic Asylum, took place since that period : yet, year after year, votes of thanks were rendered to them, their merits and services to the charities vaunted, and their names blazoned, as ornaments to humanity, in the newspapers ; and what was most extraordinary is, that then, as well as now, most of our public charities were models of preaching, praying, and psalm singing.

The whole history of these proceedings presents a most extraordinary picture of hospital neglect and defective administration, and attests the necessity of some legislative measure to guard against their recurrence : it is not enough to leave the management to the subscribers ; the previous facts shew how unfit they are for this duty, and we all know here how often party spirit, religious feuds, bigotry, and ignorance, combined with a total indifference as to details, disqualify them for such a task. They subscribe from one motive or another ; some from vanity or ostentation, others to have a right of providing for their servants or dependants in the hospital when sick, and a few from a higher and more benevolent impulse. They take no interest in the application of the machinery, and only muster on some field-day, when a friend is to be put in or an enemy ousted, or when some cause of excitement prevails, such as an election, and then, provided they come from the church or corporation party, they are sure of being carried triumphantly through. The whole system is one of *feeding and backing*, without any other principles or motives of action.

Now, then, the question comes—ought the certificates of such hospitals to be received without some other condition, or restriction, besides a certain number of beds ; ought not some proof to be required of their ge-

neral management, of the number of times that the patients are seen in the week by their medical advisers, and of regular and daily records of the cases being kept? These things ought to be looked to by those whose duty it is to do so. They may appear trifling and unimportant, but they are of the greatest consequence to the sick and to the pupils: even to this very day, the laws and regulations of our Infirmary require the patients to be seen only twice a week, though, I believe, some see them oftener; but such things ought not to be left, as works of supererogation, to the caprice or taste of the medical men. The patients are seen every day in the large hospitals on the Continent, in Ireland and Scotland, and, I believe, in London; and why should it not be so in the provinces in England—particularly when it is now contemplated to place them, in respect to qualifications for degrees in surgery, on terms of equality with the London hospitals, or those of other capitals, where the means of instruction are so infinitely superior to any thing in this respect that the provinces can afford?

I wish now to make one or two observations on the conduct of the Committee of the Liverpool Infirmary and Asylum, before I close this part of my subject, in the hope that they may serve as a lesson to others not to imitate their example. It is strange, that during the existence and perpetration of these abuses in our Infirmary and Lunatic Asylum already alluded to, that they always threw themselves into the breach to justify or conceal them, and never, as a body, raised their voices in reprobation of them, but, with the spirit and doggedness of thick-and-thin partisans, opposed, year after year, any change for the better in the constitution of these establishments; not from any gratuitous or wanton love of mischief, but because the attempts to reform them proceeded principally from those they deemed their political opponents, and the maxim was to put them down, no matter by what means or under what circumstances, although that Committee is usually composed of the principal merchants and parsons of the town: one could scarcely believe that they could or would lend themselves, in the cause of charity and humanity, to such petty and unbecoming passions; and yet, when they pleased, and had an object in view, no

persons knew better how to arraign their medical men, and make the charity the pretext for doing so. Not long since, they affected wonderful zeal for the morals of our medical men, and summoned before them the physician of the Lunatic Asylum—not for any neglect or inattention to the patients there, or for any incapacity or unwillingness to do his duty to them; but because he was said not to have examined a private patient, who was labouring under some uterine irregularity, with all the delicacy and tact of the saints in the profession. The gentleman was honourably acquitted, and the necessity of the examination justified by some of the first practitioners of the day. At the bottom of all the manoeuvres in this business were two medical men—one the supposed but faithless friend of the accused, the other his avowed enemy. Their principal tool was a parson on the Committee, whose duty and profession, one would suppose, ought to make him heal rather than open wounds, and cover with the mantle of charity the weaknesses of human nature, if they existed, rather than to exhibit them to the jaundiced eye of the public. They stepped out of their way, and beyond the duties of their office, to take cognizance of the private acts of an individual connected with their charities, and encouraged a system of espionage and tale-bearing as destructive of morals as disreputable to the independence of the profession; and all this was done by the Committee to gratify the private feelings and views of one or two of its members, though they never opened their eyes to the more glaring and obvious defects of their public establishments. They never, for example, sought to do away with the rule that requires the patients to be seen by the medical men but twice a week, and oblige them to see them every day, and keep regular registers of their cases; nor did they ever seek to do away with the rule that admits patients but once a week into the Infirmary, and thus fills its beds with old chronic cases, and excludes the great mass of the more important and acute ones. And again they never sought to diminish the number of gentlemen's servants that are received in preference to others, and that fill so large a number of beds. If they made these and other changes of equal importance, they would indeed be doing good, and multiplying,

at no increased expense and very little additional trouble, the utility of the Infirmary.

However, we are not altogether without changes in our medical usages here. Some years ago, a chaplain of the established religion was appointed, at a salary, to the Infirmary, as a panacea for all its defects, though the greater part of the inmates never trouble his ministry nor belong to his creed, being generally dissenters of one denomination or other. I wish he would use his spiritual influence with his brother clergymen, to effect some of the changes mentioned above: this would be doing something for the money of the subscribers, and fulfilling the avocations of his profession in extending the works of charity; and I believe, from his character, he is well inclined to do so.

We have also had some changes, within the last few months, in the qualifications of candidates for the office of physician or surgeon to the Infirmary: heretofore they may have practised, and did practise, pharmacy; but now they are not allowed to do so. Perhaps this is for the better; but the object of the alteration was to shut out, under the pretext of improvement, the great body of the practitioners here, who, almost to a man, are general practitioners. The surgeons of the Infirmary never suggested such an alteration until the other day; and, it is supposed, from no other motive but to enable one or two hangers-on of the corporation and church party, who are the next on the list for promotion, to walk over the ground when the next vacancies occur; and yet the only effect of this alteration will be, as it is, an understanding with some of the druggists to supply the medicine at prices previously arranged between them, leaving a fair and reasonable profit to both parties. Had they made a law that they should be what are termed "pure surgeons," then, indeed, they would shew some consistency; for what is the use of preventing them from making up their own medicines, if they be allowed to practise midwifery, as all our Infirmary surgeons do here? It is a mockery of legislation, and gross affectation, to allow them to practise midwifery and not pharmacy. To make them give up both, would indeed be of incalculable benefit to the patients and to the profession. The practice of midwifery, medicine,

surgery, and pharmacy, is rather too much for one head, generally speaking, and particularly for the surgeons of large hospitals. Just conceive some serious accidents brought in, requiring the immediate personal attendance of the surgeon, and that he, instead of being able to come, and to afford the assistance which he promised when he took office, and which the sick require, sends back word that he does not know when he can come, being in attendance on a lady in *her accouchement*. This is no imaginary case; it is of frequent occurrence and of disastrous consequences; and ought to be prevented by the very simple means of allowing no hospital surgeon to practise midwifery; and this, not from any disrepute being implied in doing so, but because it is physically and morally incompatible with the regular and proper discharge of his hospital functions. There ought to be none but pure surgeons, as the phrase goes, attached to them. They exclude here physicians practising midwifery from these appointments—nay, from the very Dispensaries—and allow the surgeons to do so! as if what applied to one, in this respect, did not apply, with ten times more force, to the other. It is a curious fact that there is, and has been for many years, but one "pure surgeon" in this great town; all the rest practising medicine in all its various departments—physic, pharmacy, surgery, and midwifery; all keeping open shops or private surgeries; in a word, general practitioners. No change was ever contemplated in this system till the other day, when the practice of pharmacy was made a disqualification for the office of surgeon or physician to the Infirmary.

I have in this sketch pointed out some defects and abuses of our provincial hospitals, that seem to me well deserving of the notice, not only of the subscribers, but of the College of Surgeons, and forcibly to illustrate the necessity of some other condition being attached to their certificates besides a certain number of beds. In order to avoid the continuance or recurrence of some of these malpractices, the legislature ought to interfere, and take some part of their general management from the subscribers.

Liverpool, Oct. 10, 1834.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Lectures on the Ordinary Agents of Life, as applicable to Therapeutics and Hygiene; or the Uses of the Atmosphere, Habitations, Baths, &c. in the Treatment and Prevention of Disease. By ALEX. KILGOUR, M.D.
1 vol. 8vo. pp. 283.

Why the author of this work should have chosen to bring it out in the shape of lectures, we cannot well conceive; especially as we presume the said lectures were never delivered, and of course now never will be. It was bad taste, to say the least of it; for, even supposing the materials of the volume had been delivered *ex cathedra*, they would still have required much pruning to make them a good reading commodity, which, we are sorry to say, in their present form, they are not. The style is colloquial; and but too often, when the author intends to be facetious, he is indelicate and coarse. For what class of hearers or readers he intended his lectures, it is not very easy to say for certain. In his lengthy and desultory preface, he informs us, in one place, that they are designed for the profession; but from the title of the performance, and the popular manner affected throughout, we should fancy he rather had the good of the public at large in view. And indeed this seems to “stand confessed” at p. xxii. of the said preface.

“Antyllus tells us,” says our author, “that to relieve the sickness from a dose of hellebore, the patient should be entertained with some funny little story. Oftentimes a medical work is as sickening as a dose of hellebore, and the student has reason to pray that the author had introduced occasionally the *lepida fabella* for him, as well as recommending it for his patient. I have not always walked on the professional stilts; and if the non-professional person attempt to read my work, I hope he will not find that I have catered to the diseased fancy of hypochondriacs, or called up an awful array of rules for health, as if death was in every pot, and destruction in every mouthful of air.”

So much for the design and general quality of the volume. The author seems satisfied that it has been much

wanted; but let us see how he convinces himself of this.

“The importance of these agents (the non-naturals) is a piece of knowledge which the young practitioner only acquires, in general, by some sad experience and bitter disappointment. Whilst he is pondering on the case, weighing accurately in his mind the action of each medicine he is exhibiting, and watching with intense anxiety for its expected sanitory effect, the patient will quit this world with the medicine very likely in his bowels, but along with it some solid and substantial article that would require the digestive powers of the healthiest stomach. A hard bed is a hard thing to a healthy person, and more especially to a *fat female dowdy*, who measures all others' comforts by her own; and where rest might be life, death is hastened by following the advice of this feeling hearted soul, in moving the patient for the purpose of shaking up *his* bed. A free ventilation might soon put him on his legs, and it would for certain expel effluvia; but open windows let in the cool air, and cold air is better felt than contagious effluvia: so the windows being kept shut, and the bed-curtains drawn close, the patient has the happiness of dying in an atmosphere of his own creating, raised to a proper putrifying temperature by means of a blazing sea-coal fire. What can we think of the man who, in circumstances like these, calls for paper, pen, and ink, in order that he may *scrawl a receipt, in indifferent Latin, for worse medicine*, and knows not to order that which would relieve the patient without pain or expense?”

Why—“indifferent Latin,” and “worse medicine”? What have these to do (even if they were so common as Dr. Kilgour seems to think), with an ignorance of the *non-naturals*? But this sort of gross exaggeration, which we frequently meet with in the volume, we beg leave to tell the author, however it might pass off flippantly in a lecture, is as unbecoming as it is unwarrantable, when deliberately set forth in print. Where can Dr. Kilgour have seen the “young practitioner” in such a state of stupid ignorance setting about the business of his profession? Where are such “young practitioners” licensed? It is surely not *south* of the Tweed; and if such be the worthies in whose behalf the Doctor has published his lectures, he would have done wisely in sparing himself the expense of forwarding any copies in this direction.

But we perceive that the author's

kind consideration extends to us as well as to the "young practitioners" of his own country.

"In England, the article of diet is held of some importance; but even the acquaintance with *this one* is not complete. The practitioner knows that, in acute disease, his patient should not have beef, nor beer, nor strong soups; but this is about all he does know on the subject. Low diet and perfect starvation are with him almost synonymous terms; and what he, at the very utmost, understands by a change of diet, is merely a transition from beef to bread, and from soup to gruel. Of the effects of the different kinds of food he knows nothing."

If this be the case, Dr. Kilgour's lectures ought to be quite a godsend. But sober truth obliges us to say that, English and ignoramus as we are, we have in vain sought for anything new or original in the volume before us. If, however, our search has been unproductive in finding things merely new, it has not been so in respect to things surprising and singular. For example, who would expect to find, in the lecture on clothing, such an animated expostulation as the following? Dr. Willich, in his observations on dress, quotes a Dr. Faust, an eminent German physician, who argues against the use of *breeches*, but denies the conclusiveness of the learned German's argument. Dr. Kilgour, however, conjectures that Faust "perhaps lost his breeches, metaphorically speaking," and then bursts out into the following elegant protest:—

"Good heavens, give up our breeches! No, neither for Dr. Faust, nor the still greater Mephistopheles; neither for Faust, the disciple of the Devil; nor this Faust, the disciple of Folly!"

On the subject of *stays*, concerning which we have had disquisitions and discourses *usque ad nauseam* from many a learned pundit of late, our author is as copious as any of his predecessors; and so much in earnest about it, that in the solitary lithograph which adorns his work, he copies from the Penny Magazine some illustrative figures, which that periodical copied from Soemmering.

The chapter on Exercise contains a good deal of amusing matter, but much precious time is wasted in telling us that "in leaping the shock is much greater than in walking, in proportion to the height which the body has been

raised from the ground;" and that in riding, an invalid ought to prefer a she-ass to one of the other sex, "as, besides carrying the invalid, it will furnish him with her mild and easily-digested milk," &c. The account, however, of the *training process*, which closes this chapter, is interesting; the reader will not fail to notice, at the same time, the style of the description.

"The most flabby and shaking sot of a tap-room will be, in three or four weeks' training, made as *pretty* and powerful a man as can be seen of his *inches*. All this is achieved by pure air, by nourishing food, and by exercise. The trainer takes his man to an open, and, if possible, a hilly country; he *cleans out* his stomach and his bowels once or twice with an emetic, and a warm and resinous purgative; he takes him from bed every morning at six, and exercises him in walking, running, leaping, riding, or a part of all, for three or four hours at least; he then breakfasts him on a beef-steak, stale bread or biseuit, and a little tea or milk. Exercise is again had recourse to, either as before, or with the gloves, the balls, the dumb bells, or quoits. The dinner is beef-steaks, or joint of mutton, or lean chop, stale bread, and a little beer. Exercise is again followed for three or four hours in the open air, and then supper of steaks and stale bread. The bed is hard, and the length of sleep not above seven hours. He has no idleness of mind or body; he must be always occupied, and it is best to engage his mind with the exercises of his body. He eats but three meals a-day, and the solids must be nothing but the lean of fat beef, mutton, or venison. The legs of fowls are sometimes allowed for variety, but no veal nor pork. The meat must always be broiled and under-done. Stale bread is almost the only vegetable substance allowed; sometimes a little potatoe, but no *herbs*. Eggs are occasionally taken, but no cheese, nor butter, or fat of any kind. The quantity of solids allowed during the day will depend upon the stomach and constitution of the individual, but must always be rather *below his usual quantity*—seldom, in any case, above twenty-four ounces. No condiments are allowed, with the exception of salt, and that only in a very small quantity. Fluids are considered as injurious. No food is given in this form; and, for the purposes of alleviating thirst, and supplying the necessary waste of the fluids of the body, soft spring water is the best. No spirits are allowed, but occasionally a little porter after dinner or supper. The quantity of fluid, of any kind, taken during the twenty-four hours, must not exceed, in all, three English

pints. Exercise of that kind in which the trained person is to exhibit, must form a large part of his daily occupation."

We have said that parts of this work are coarse and indelicate: much of the last section on the secretions is grossly so; and we are at a loss to comprehend for whose benefit it was written, if not for that of certain non-professional debauchees of most depraved appetite: surely not for the medical profession, or even the youngest of practitioners. The author probably would excuse himself by referring us to the anecdote of Sterne and the lady (which, by the way, he mangles sadly in the telling—as he also does another relative to Mr. and Mrs. Shandy); but, beside that we cannot exactly concede to Dr. Kilgour the same privileges that we do to the inimitable Yorick, we question if there be, in the whole range of the works of the latter, any thing to equal the indecency of Dr. K.'s concluding lecture.

One word more. We would recommend the Doctor, when next he quotes the *Greek* writers, to do so less frequently in *Latin*: he might as well give us Ambrose Paré or Morgagni in Scotch. And when embellishing his text with poetical beauties, we would have him at least know to what author he is indebted, and what that author is speaking about. For example:

"The poet was not so far wrong when he said, in *satire*, of a *fashionable female*, that she would

"*'Die from [of] a rose in aromatic pain;'*" &c.

We thought every school boy knew that the poet who wrote this exquisite line (exquisite when taken in its proper sense and unmitigated), had neither "*satire*" nor "*fashionable female*" in his head when penning the passage to which it belongs. Would Dr. Kilgour have the kindness to look into Pope's *Essay on Man*, first epistle—and blush for his transgressions?

A Manual of Aphorisms in Chemistry; the Chemico-pharmaceutical Preparations and Decompositions of the London Pharmacopæia; and Toxicology, &c. By ROBERT VENABLES, A.M. M.B., OXON.

THE student will find this a very useful little work. It comprehends a great number of the most practical facts in

chemistry, pharmacy, and toxicology; and will be particularly available for imprinting on the memory what has been already learned at lecture, or from class books. In some instances, indeed, the author is even in advance of the present state of class-book knowledge. We shall give an example, which will serve at the same time as a specimen of the style in which the manual is composed.

"127. The most important of the narcotic poisons are opium and hydrocyanic acid.

"128. Opium may be detected by testing, either for its morphia or its meconic acid.

"129. Morphia, if treated with nitric acid, becomes red; with permuriate of iron, it dissolves and forms a dirty indigo blue. It decomposes iodic acid, setting the iodine free, which may be detected by starch.

"130. Meconic acid forms, with sulphate of copper, an emerald green colour; and with the persalts of iron, a red. Upon these properties principally are founded the means for detecting opium.

"130. Sulpho-cyanic acid communicates also a red colour with the persalts of iron, and therefore might be confounded with meconic acid; but the precipitate, with nitro muriate of gold, distinguishes it."

Dr. Venables is here, we believe, in advance of Christison, in noticing the properties of sulpho-cyanic acid in connexion with the meconic acid. It may here also be observed, that the aphoristic style has its defects as well as its advantages: *brevis esse laborat, obscurus fit*. The author might have added one little piece more of information, without much increasing the bulk of the last aphorism. He might have stated that sulpho-cyanic acid, or at least the sulpho-cyanuret of potass, is a constituent of human saliva,—which would at once impress on the student the importance of noticing this substance in juxta-position with opium.

A Compendium of Pharmacy, explanatory of the Chemical Decompositions of the Pharmacopæia Londinensis; illustrated by Diagrams. By WM. MEADE, M.R.C.S. &c.

THERE is a good deal of useful information comprised here in small compass. Students of pharmacy will find it a convenient hand-book, and we recommend it to them accordingly.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ lueri: potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

TREATMENT OF THE PROPENSITY TO SUICIDE.

Our magistrates have lately, in several instances, adopted the practice of inflicting punishment on persons caught in the act of making away with their own lives. The design is excellent and humane, and the result, we believe, in general has proved highly satisfactory. It often happens that a wretched person, resolved on self-murder, only requires to be checked on the verge of the precipice to be made sensible of the enormity of the crime he is about to commit. Others are helped to the same conviction when they have had one cooling-plunge in the water in which they intended to perish, but with the chance of safety still within their reach. Others, again, are brought to their senses by being put under a temporary restraint, and perhaps being favoured with a little leisure for reflection while treading the wonder-working Mill. This was the remedy prescribed a few days ago, by a police magistrate, for a woman, who, in a fit of drunkenness and vexation, flung herself into the London Dock. A short residence at Brixton will, no doubt, do her much good.

Judging from what we know, and have heard, of persons interrupted in their purpose of suicide, it seems probable that, in the great majority of cases, there is only required some obstacle, however slight, to divert the attention of the suicidal desperado, and to break the current of his thoughts. The story is currently told of the man who was about to precipitate himself from the battlement of a bridge at midnight, but

was startled into sanity by the sight of a robber's pistol levelled at his head. The spell was broken: he could see at once the awful nature of loss of life by one method, though, owing to his previously-brooding thoughts, he had lost all sense of the same bereavement by another.

Imitation is a fertile source of suicide. That man is an *imitative animal*, according to the dogma of the old philosopher, is here displayed in a serious light. The annals of every people and race on the face of the earth have something—some calamity of this kind—to quote in illustration. In the olden time, the ladies of Miletus, in a fit of melancholy for the absence of their husbands and lovers, resolved to hang themselves; and vied with each other in the alacrity with which they did the deed. In the time of the Ptolemies, a stoic philosopher pleaded so eloquently one day, to an Alexandrian audience, on the advantages of suicide, that he inspired his hearers with his principles, and a multitude of them voluntarily gave up their lives. The young women of Marseilles were, at one period, much in the habit of making away with themselves; but a law being passed, that the body of every female who committed suicide should be publicly exposed after death, the folly ceased—the sense of shame prevailed over the recklessness of life. Tarquin nailed on crosses the bodies of those who flung themselves off the Capitoline Hill, in their despair at the hard work imposed upon them: the disgrace of being crucified after death, cured the propensity. But these are instances in which some cause, more or less plausible, can be assigned for the rashness of the parties: there are others in which the actuating motives are wholly mysterious; where the suicides follow each other in quick succession, as sheep jump after their leader. Sydenham tells us, that at

Mansfield, in a particular year—in the month of June—there was quite a crowd of suicides; the cause being wholly unaccountable. The same thing happened at Rouen, in 1806; at Stuttgart, in the summer of 1811; and at a village called St. Pierre Monjean, in the Valais, in the year 1813. One of the most remarkable epidemics of the sort, however, was that which prevailed at Versailles, in the year 1793. The number of suicides within the year was 1300,—a number out of all proportion enormous for the population of the town. It can scarcely be argued that “the reign of terror” will account for this; for in Paris, at the same period, the number of suicides did not exceed the annual average; and many other towns of France were as much agitated as Versailles during the Revolution, without being characterized by a similar catastrophe. There is no other reasonable way of accounting for the circumstances than by attributing them to the influence of a blind imitation. Suicide, no doubt, occurs most usually in isolated instances; but we cannot help being struck with the extraordinary fact, that sometimes examples of it are so numerous and simultaneous that it can only be compared to the irruption of a contagious epidemic malady.

Nor is the disposition to imitate less remarkable in the *mode* of suicide. Sometimes, as at Miletus, it is the rage to hang; sometimes to drown, as the women at Lyons did in abundance towards the middle of the last century; or as the “rash intruding fools” in the London Docks have done frequently of late. Sometimes it is the fashion to use the pistol, which began to be much the practice in polite Europe about the time that Goethe's Werther caught the public taste. Some years ago oxalid acid was a favourite poison, as prussic acid often is at present: and the Parisians, it may be added, at one time vie with each

other in pitching headlong from high places; while at another they prefer to asphyxiate themselves with the fumes of ignited charcoal.

It is rather amusing, however grave the subject, to find some of our French contemporaries endeavouring to account for the late frequency of suicides in Paris. It was once the custom for all their philosophers, including Voltaire, Montesquieu, and their host of disciples, to give us English the palm of superiority on this point—the only point, perhaps, on which they would give us precedence. Any allusion to the gloomy month of November was enough to raise an association of ideas in which the English, the blue devils, and hanging or drowning, were most prominent. Statistical information, however, has much disturbed these theories in latter years; and the fact that the number of suicides in Paris is to that of London in the proportion of above five to two annually, has given room for much refined speculation.

“The external circumstances,” says a late French writer, “which tend to suggest the idea of suicide are very numerous at the present day in France, but more particularly so in the capital. The high development of civilization and refinement which prevails here—the clash of interests—the repeated political changes—all contribute to keep the moral feelings in a perpetual state of tension. Life does not roll on among us in a peaceful and steady current; it rushes forward with the force and precipitation of a torrent. In the terrible *mêlée* it often happens that the little minority, which has obtained a footing high above the multitude for a time, fall down as suddenly as they have risen. The struggles of life are full of miscalculations, disappointments, despair, and disgust. Hence the general source of our frequent suicides. But there are other causes in operation; and not the least,

among them, the strange turn that stage plays and spectacles have latterly taken. The public taste has undergone a complete revolution in this respect. Nothing is more patronized now at the theatre than the display of crime unpunished, human misery unconsolated, and a low literature, impregnated by a spurious philosophy, declaiming against society, against domestic life, against virtue itself; applauding the vengeance of the assassin; and recognizing genius only as it is seen in company with spleen, poison, and pistols. We appeal to all who read the novels of the day, and who visit the theatres, whether what we say is not the fact."

If this be a true picture (and we believe it is) of the high state of *civilization* and *refinement* of "young France," we cannot wonder at the propensity so strongly manifested by numbers of individuals, thus *refined*, to part with life in their moments of ennui. We doubt, however, whether the expedient proposed by the writer just quoted would have all the effect intended. He feels, as well as ourselves, that the tendency to imitation, so deeply implanted in our species, has much to do with the perpetration of self-murder; but *he* thinks that the only remedy to be suggested is the suppressing, on the part of the newspapers, the frequent accounts published of individual instances of the crime. Even were this possible—and few will maintain that it is, knowing how public journalists are ever rather led by, than leaders of, the public taste—it could go but a short way in suppressing the propensity. The true way to set to work is to watch for individual instances of attempts to make away with life, and in every case to punish rigorously, as would be done on the detection of a culprit found proceeding with an intent to commit any other kind of felony. We confidently anticipate that the good that will be effected by persevering in

this method will soon abundantly satisfy the most sceptical.

We are not of the number of those—and there are distinguished names among them—who hold that the very act of suicide itself is a proof of the perpetrator's insanity. Did we admit this, we could not refuse the same plea in extenuation of almost any other capital offence. At the same time, let it by no means be supposed that we would deny the existence of a suicidal monomania. Our view of the matter stands simply thus:—Suicide can in many cases be traced to hallucinations or illusions of the mind, to chimerical fears or imaginary griefs: here there is no room for question. But in the great majority of cases we have reason to believe that self-murder is decided on in consequence of no merely fanciful mental affections: some reverse of fortune has happened; some darling object of ambition or love has been irrecoverably lost; some disgrace is incurred or is dreaded; and numerous other motives, many of them disgusting, the offspring of depraved and vulgar habits, might be enumerated*. What is suicide, when committed under any of these circumstances, but an act dictated by the passions, in contravention of the laws of the community, and no more to be excused on the ground of insanity than any other crime proceeding from the same source? Reason itself is manifestly, to a certain extent, concerned in it; a calculation—a balance of evils, is indeed instituted; but the *passions* determine. Will any one contend that the play of impulses so dangerous should be endured, and permitted to disturb society with impunity?

The reprimand of the magistrate has often acted, on such occasions, with

* Foderé mentions the story of an Englishman who advertised that he would, on a certain day, put himself to death in Covent Garden, for the benefit of his wife and family. Tickets of admission a guinea each.

good effect. When Buonaparte heard of some one or two instances of suicide occurring among his troops, in the year 1802, he issued forthwith a proclamation *; which doubtless, had it not proved effectual, would have speedily been followed up by measures more summary and prompt. We give the document below, not for any originality in the fine moral lesson which it inculcates—for the sentiments will be recognized as at least 2000 years old—but because it shews how this extraordinary man considered the propensity to suicide as not beyond the reach of control, and that it was *his* policy to meet it by a check direct—not by suppressing the notice of it through any fear of a dangerous example. If the same policy which has been so laudably commenced here, be only steadily acted upon, we shall hope ere long for the happiest results. If, however, the reprimand do not seem, in certain cases, likely to have due effect, punishment—that of solitary imprisonment, with occasional labour—will scarcely fail to be efficacious. The crime, let it be remembered, is at least the *attempt to commit a capital offence*,—a felony against God and the king, “who has an interest in the preservation of *all* his subjects;” and if punishment be not dealt out to the wretched culprit, for his own correction, the infliction of it is surely demanded for the warning and edification of others.

* *Order of the Day. St. Cloud, 22 Floreal, an. x.*
—The grenadier Groblin has committed suicide, from a disappointment in love. He was, in other respects, a worthy man. This is the second event of the kind that has happened in this corps within a month. The First Consul directs that it shall be notified in the order of the day of the guard, that a soldier ought to know how to overcome the grief and melancholy of his passions; that there is as much true courage in bearing mental affliction manfully, as in remaining unmoved under the fire of a battery. To abandon one's self to grief, without resisting, and to kill one's self in order to escape from it, is like abandoning the field of battle before being conquered.

BESSIERES.

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

By PROFESSOR MAYO, F.R.S. &c.

I.—Of Fractures, and their Union.

IN the process of union after fracture, two forces manifest themselves; one of which is developed in the tissues which surround the broken bone; the other originates in the bone itself.

The first of these forces is the ordinary agent in repairing fractures; that is to say, it operates in uniting fractures,—of the long bones, with the exception of those parts which are contained in synovial cavities, and of those instances in which fracture is unattended with rupture of the periosteum,—of the round bones generally,—of the flat bones, with the exception of those of the cranium.

The second comes into operation in the cases which form the exceptions above stated.

I.—The process of reparation, which originates in the surrounding tissues, has hitherto been minutely studied in one class of fractures alone; in those, namely, of the shafts of long bones. But enough has been observed of the phenomena attending the other instances specified under the first head to make it probable that they fall under the same law.

In the reparation of simple fractures of the shafts of long bones, five periods may be distinguished.

1.—The first occupies the three days succeeding the fracture. If a limb is examined in a case where death has ensued a few hours after a simple fracture, the following appearances are met with. There is commonly little extravasation. The soft parts adjacent to the broken bone appear bruised, and in a state of ecchymosis. The medullary membrane near the fractured surface has the same character. The periosteum is stripped irregularly for a small distance from the edge of the fractured ends. During the three days which follow the injury no change takes place in the condition of the parts beyond a commencing absorption of the small quantity of extravasated blood. In cases in which, from the rupture of a vessel of any magnitude, much blood has been poured out round the fracture, the process of reparation is retarded; it must wait the absorption of the blood. For any thing which takes place immediately around a fracture, its setting during the first three days is not requisite. What renders the early setting necessary is the contraction of the muscles,

which, if not from the first counteracted, is sure to lead to the shortening of the limb. General and immediate swelling of a broken limb, which prevents the ordinary process of setting, answers, at the same time, the same purpose, by keeping the limb stretched to the full length.

2.—The second period extends from the fourth or fifth, to the tenth or twelfth day. About the fourth day the textures surrounding the broken part of the bone become infiltrated with coagulable lymph. The process which causes this is closely allied to inflammation. The parts become more vascular; and lymph, like that effused upon an inflamed serous membrane, is sometimes found upon the ends of the broken bone. The parts around being thickened, there is less freedom of motion at the fracture. The thickening appears to involve every tissue equally; but its especial seat is the cellular membrane.

The adjoined figure, taken from the tibia of a rabbit, killed six days after the fracture, is intended to convey an idea of the general thickening then present. The

letter A is placed upon parts of muscles divided longitudinally, where the fibrous structure could scarcely be discerned for the opaque gelatinous effusion into their substance.

3.—The third period extends from the twelfth to the twentieth day. During this period the muscles, tendons, nerves, and sheaths of vessels, which have been involved in the common infiltration with lymph, disengage themselves from the general thickening, and become external to a dense opaque capsule, the *callus*, as it is termed, which surrounds the fracture adhering to both portions of the bone at a greater or less distance from the line of fracture*. The tendons frequently lie in grooves upon the callus, and sometimes are contained in channels running through it. The quantity of callus appears to be determined by the quantity of injury done to the bone, and by the gentleness or roughness with which the part may have been treated. An oblique fracture with one or more separated fragments, for instance, and a broken bone which has passed undetected, will have more callus than a transverse fracture, or one set at once.

4.—In the fourth period, which extends from the twentieth to the thirtieth, fortieth, or sixtieth day, according to the health and vigour of constitution of the patient, the callus becomes cartilaginous, and then rapidly ossifies. The adjoined figure, taken, like the preceding, from a preparation in the Museum of King's College, exemplifies this stage of union. The letters AA are placed upon the callus, which is now cartilage in progress of ossification. A distinct membrane, continuous with the periosteum of the sound bone, covers the cartilage. The callus, in this instance, is of unusual thickness. The substance B, which intervenes between the broken portions, is organized, and its vessels are injected; but it is soft, like lymph upon an inflamed pericardium. It is in this stage of union that a limb, which has been broken, begins to be used. The fracture is sometimes so pliant to the end of this period as to allow any crookedness or deformity from bad setting to be rectified.

5.—The fifth period extends from the termination of the preceding to the sixth month. It is characterized by the extension of ossification into the soft substance, which directly unites the broken extremities. The bone so produced is ex-

* There are four opinions as to the source of callus: that it is produced by the periosteum; that it is an exudation from the extremities of the broken bone, particularly from the medullary membrane; that it is derived by direct growth from the animal structure or vessels of the bone; that it originates in an infiltration of the textures adjacent to the bone. The first is the opinion of Duhamel; the second, that of Haller; the third, that of Baron Larrey; the fourth, that of M. Dupuytren. With the last my own observations concur. The account in the text is founded upon M. Sanson's account of M. Dupuytren's theory and my own experiments.

tremely dense and compact. As this change proceeds, the ossified callus surrounding the fracture is gradually absorbed. The final restoration of the bone to its original state is completed subsequently by the formation of cancelli in the dense structure at the plane of union.

The changes which have been described are an effort of Nature towards the restoration of a broken bone: that effort requires to be seconded by art. The broken extremities must have no motion on each other, or they will not unite at all; they must be kept in correct apposition, or the result, if they unite, will be deformity.

In the Museum of King's College are preparations of want of union, or *false joint*, after neglected fracture of a rib,—of the fibula,—of the ulna,—of the radius,—

of the lower-jaw,—of the neck of the femur. Motion seems to prevent the callus becoming cartilage; it is converted instead into a fibrous capsular membrane. The ends of the bones within this capsule are sometimes partially united by soft substance; in other instances they freely move upon each other; the opposed surfaces being partly smooth bone of unusual compactness, partly soft white fibrous substance. The friction of the bony extremities moving on each other causes them to enlarge, so as to produce broad articular surfaces,—flat, if the fracture has been oblique,—often concave and convex, if the fracture has been transverse.

The effort towards restoration is transitory. When a false joint has once formed, rest alone is insufficient to repair it, and to produce bony union. But it is possible to excite a fresh action round the fracture; the result of which, assisted by rest and bandaging, will produce consolidation of the parts. The most certain means of re-exciting a salutary action, are the introduction of a seton between the surfaces of the false joint, as recommended by Dr. Physick, of New York, and the keeping it there till the false joint begins to stiffen.

In practice, the prevention of motion at the fracture is secured by the means which provide for the correct apposition of the extremities of the broken bone. The cause which tends to counteract a correct adjustment of the broken portions is the action of the muscles. In some cases, as in fracture of the patella and of the olecranon, and of the lower jaw, the action of the muscles separates the fractured ends: in others it draws them too forcibly together, causing the one to ride over the other, so as to shorten the limb. The most perfect apparatus with which I am acquainted for any case included in the first class, is Mr. Edward Lonsdale's instrument for fractures of the lower-jaw. In the second class of cases there are two principles, on which splints and bandages may be applied with success to prevent shortening. One is their application with a permanent purchase upon both ends of the fractured limb. This is exemplified in the use of Dessault's splint in simple fractures of the thigh. The other turns upon the following law of muscular action. When a muscle shortens, it gains exactly in breadth what it loses in length. If, then, a broken limb, (the arm, for instance, after fracture of the humerus,) be extended to a proper length, and firmly bandaged, (splints to prevent flexion of the fracture being interposed between the reduplicatures of the roller), shortening will not take place; for the unyielding nature of the bandage is a sufficient impe-

diment to that lateral swelling, without which the muscles cannot contract.

II.—Of the instances in which union takes place through the forces inherent in the bones themselves, the most remarkable are fractures of the cranium.

When a cranial bone is broken, no condensation of the adjacent textures takes place—no callus is formed. The final cause of this negative phenomenon is obvious. If a callus were formed along a fracture of the cranium, although on the exterior it would be of little consequence, on the interior it would constitute a tumor, that would compress the brain and disturb its functions. It is more difficult to assign the physical cause. It is plausible to say that the cranial bones are incased in pericranium alone, and thus are not surrounded by the textures, the thickening of which gives rise to callus. But this explanation does not apply to fractures of the temporal bone, or of the basial part of the os occipitis; and I am not aware that these bones unite more favourably than, or differently from, others of the cranium. The fact, therefore, remains an isolated one, and reduced to no principle,—that the cranial bones do not unite by callus. They are left to their own forces for restoration, and the forces operate very slowly. There are two preparations in the King's College museum, which exemplify the process by which cranial are repaired: one is a skull from which a portion had been chipped by the blow of a sabre on one side, and the bone simply cut through on the other. The second is the skull of a person who had been trephined six years before his death. In each of these instances the holes made in the cranium were in progress of being filled up by a gradual extension of thin bone, from the cut, but now rounded edges, stretching across the interval.

A second illustration of the ossific forces inherent in bone is found in fractures of the neck of the femur within the capsular membrane.

Sir Astley Cooper has shewn how commonly, in such cases, bony union fails to take place. In general, either there is no union at all, or the union is by soft fibrous substance. Both these contingencies are exemplified by preparations in our museum. In a case in which there was *no union*, the head of the bone had adhered by soft fibrous substance to the brim of the acetabulum, in which it was firmly fixed. The neck of the femur had been nearly absorbed, but its stump had rested against, and moved upon, the fractured surface of the head of the bone; a capsular membrane extended from the margin of the acetabulum to the trochanter major; the

surfaces of the false joint were hard and polished, of porcelain bone. In another case, in which the patient died suddenly of apoplexy, thirteen months after fracture of the neck of the femur, *ligamentous union* had taken place. An interesting point in this specimen is the existence of a small ossified callus, exterior to the capsular membrane. It appears evident that the adjacent tissues had commenced the sympathetic process of restorative action first described; which, however, was nugatory, as it could not penetrate through the synovial cavity, to connect itself with, and stretch into, the soft substance which directly united the fractured surfaces. This case had been treated with care in the Middlesex Hospital; the joint had been kept perfectly still: the result was ligamentous union. The patient lived long enough to shew the inability of an isolated bone to form a callus; but not long enough to give time for the extension of ossification from the bone itself.

The fact, however, is well authenticated, that union by bone will sometimes ensue after fracture of the neck of the femur within the capsule. The principle, upon which such union takes place, is the same upon which cranial fractures are united. The process is an extension of ossification from the ends of the broken bone into the connecting soft substance. As this process is extremely slow *here*, as in the cranial bones, and as fractures of the neck of the femur commonly occur at an advanced period of life, it is not wonderful that specimens of bony union in this part are rarely met with.

CLINICAL LECTURE

ON

FRACTURE OF THE PATELLA.

BY BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

FRACTURES of the patella present several points of interest to our examination, regarding which authors are not agreed: such, in particular, are the mechanism by which they are produced, the method of treatment, or the apparatus which is most applicable, the manner in which the callus is formed, and, above all, the possibility of effecting an union of the fragments without any intervening medium.

Six patients, with fractures of this kind, have been recently treated in the Hôtel Dieu: all presented a transverse solution

of continuity; five were perfectly cured, without the slightest deformity remaining, the use of the limb having been entirely restored. One is still under treatment. In this last, the fracture was the result of a fall upon the left knee, with a good deal of swelling, caused by extravasation of blood into the soft parts and into the joint. Nevertheless, there was no difficulty in recognizing the nature of the injury. The finger run along the patella encountered a considerable depression where the bone was separated into two portions—one above, the other below. They could be moved in opposite directions, and approximated by the extension of the limb, while crepitation was produced by their friction. Notwithstanding the severe complication of the fracture, the patient has rapidly advanced towards recovery. But that happened which M. Dupuytren has often observed in other cases; the bandage intended to keep the fragments in apposition, only acting upon the skin, forced this between edges of the bones, thus keeping them apart. It was necessary, therefore, to readjust the dressings.

Transverse Fractures.—Fracture of the patella may be produced in two different ways—by force applied directly to the knee in front, or by violent exertion of the extensor muscles of the limb. However, it has sometimes taken place without the muscular exertion having been very great; as, for instance, in the act of leaping, kicking, or the effort of avoiding to fall backwards. In all these circumstances, the patella is only supported by one part of its posterior surface against the anterior face of the femoral condyles: at the same time that the limb being half bent, the inferior ligament and the extensor tendons drag the extremities of the bones strongly backwards. During the effort which then takes place, the femur serves as a point *d'appui* to the forces acting upon the patella above and below, the continuity of which gives way from without inwards.

[We beg to refer our readers to a very instructive lecture on Fractures of the Patella, by Sir Charles Bell, contained in our first volume. The point above discussed by M. Dupuytren is placed in so clear a light, that we shall insert it here.

“This kind of fracture of the patella is most frequently caused by the person stumbling, and then making a violent effort to recover his balance. He suddenly brings the quadriceps extensor into powerful exertion, and the force of this muscle may be imagined, when we consider that it is capable of throwing up the whole body as in a leap: it is this muscle, too, which straightens and then fixes the limb, when

we rise up under a heavy load placed upon the shoulders. We can therefore imagine, that in making a violent convulsive effort, when the body is thrown off its centre of gravity, this muscle may act with force sufficient to rend the patella asunder. But there is another circumstance which renders the liability to fracture greater; there is a certain degree of flexion of the knee-joint, during which the patella is more easily broken. About the middle state between extreme flexion and extension of the limb, the patella rests with its upper half upon the convex surface of the femur, while that part of the bone to which the ligament of the patella is attached, projects without support over the space left between the separating surfaces of the fe-

A the projecting part of the patella to which the ligament is attached, and which is apt to be broken off from the change in the direction of the force.

mur and tibia. If the knee joint be further bent, and the quadriceps muscle be in a state of spasmodic contraction, thus retaining the patella fixed upon the end of the femur,—and if the ligament of the patella be acting in an angular direction upon the projecting part, the bone is then snapped, as it were a stick broken across the knee.”]

A great number of these fractures have been improperly attributed to falls upon the knee. It has escaped observation, that under such circumstances the weight of the body strikes almost exclusively on the projecting part of the tibia, which receives the ligament of the patella; by the flexion of the limb to a right angle, this projection of the bone comes first to the ground and receives the entire shock, whilst the patella can only touch at its lower extremity. Falls on the knee are often the result, not the cause, of fracture of the patella; it is because this is broken that the individual falls, not in consequence of his falling that this is broken.

Cutting or bruising instruments, directed against the knee, may break the patella into fragments. This accident may also happen from a fall, if the leg be power-

fully bent, and if the bone strike violently against inequalities of the ground; but even in this case the action of the muscles has much to do in producing the fracture.

As I have above pointed out, there are perceptible differences between the fractures of the patella produced by muscular efforts and those caused by direct blows upon the knee. The former are rarely complicated with contusion, laceration of the soft part or of the joints, unless the patient fall roughly after the fracture has taken place; the latter, on the contrary, are often accompanied by extensive injury of the surrounding tissues—sometimes the patella is, as it were, shattered and reduced to a number of fragments, which are separated in every direction, while the capsular ligament is torn, and hæmorrhage takes place into it. These complications render the consequences of the injury very formidable. Here is an example:—

Examination of a Limb some time after Fracture of the Patella.—A patient, advanced in years, affected with a fracture of the patella, without much separation of the fragments, but accompanied by various untoward complications, died last November, after a considerable time with symptoms of mischief in the head and abdomen. The limb was carefully examined. At first sight the fracture was scarcely to be distinguished; the patella was moveable; a furrow, formed by the separation, was imperceptible to the eye, but sensible to the finger; this being carried from above downwards encountered a gutter, which was easily followed. The joint being opened, appeared internally of a deep red, and filled with a certain quantity of sanguineous and purulent matter; there had therefore existed inflammation, terminating in effusion. This mischief in the joint sufficiently accounts for the symptoms under which the patient sunk. The inner surface of the patella exhibited a transverse groove, but higher up than on the external surface. The bone had therefore been broken from below upwards, and from before backwards. The fragments were intimately united, nothing being interposed between them.

On the preservation or destruction of the fibrous layer which covers the patella, depends the facility or otherwise with which the fragments are maintained in their proper places, and also the solidity of the parts after the cure. In fact, this fibrous layer forms a kind of bandage, which retains the fragments opposing their immoderate separation, and serves as a basis for the material which, at a later period, is to effect their union. It may thus be seen with what attention it is ne-

cessary to manage it, and to avoid those considerable movements which are often had recourse to by the surgeon, with a view of ascertaining whether a fracture has taken place.

Vertical Fractures.—The vertical fractures are less common than the others, yet such cases are not very rare, although we find little about them in modern treatises on surgery. The oldest example (the only one, perhaps, which has been described with great precision) is to be found in the work of La Motte. The fracture was the result of a fall from an elevated situation: the two portions of the bone were slightly separated from each other, although the limb was half bent. It was placed in complete extension; the knee surrounded by compresses, and moderately tight bandaging. Consolidation was complete in twenty days, and the limb soon regained its usual strength, the callus being but little apparent.

Cases of Vertical Fracture.—About twenty years ago, I admitted into the Hôtel Dieu a middle-aged man, who had broken several bones in consequence of falling from a height. His knee was prodigiously bruised and swollen. He died the third day after the accident. On examining the limb, a longitudinal fracture of the patella was discovered: the bone was divided into two nearly equal fragments; the parts of the bone were mobile, and admitted easily of being displaced; the capsular ligament contained a large quantity of sanguineous fluid. Six months had scarcely elapsed when another man was brought to the Hôtel Dieu: he was drunk, and had been knocked down by a carriage. On the knee and thigh were to be seen the mark of the iron which binds the wheel. It had passed from above downwards over the limb, and the patella was divided in the same direction. Crepitation of the fragments was perceived on examining the limb, and the parts were afterwards retained in position by appropriate bandaging. The cure was going on favourably, when the patient was seized, without any obvious cause, with peripneumony, which carried him off on the twentieth day after the accident. The parts were examined with much care, and a well-formed callus was found, which united the fragments, allowing of but very little motion, and every thing announced a rapid recovery. Three years after, a man came to the Hôtel Dieu to be treated for varix of one of his legs. In examining the limb, I perceived that the patella was universally broad, with a vertical projection. Nothing of the same kind was seen on the other side. On questioning him as to the cause of this deformity, the patient said that some years before, he had fallen and broken

the leg and thigh in several places. The patella had shared in the mischief, and the augmentation of its size proved that the callus had acquired a considerable development. The movements of this bone were easy so long as the extensor muscles were relaxed, but at other times the friction of a considerable irregularity against the condyles of the femur was evident. It appeared that the fracture had been vertical, and that this irregular consolidation had been the result of the unaided efforts of nature, or at best of a position but ill adapted to the purpose.

The following is an example, no less important, of a fracture of this kind. A servant, 19 years of age, of small stature and feeble constitution, and who had long been affected with pulmonary catarrh, fell from the second story to the ground. Striking against the pavement, she received a wound upon the left knee, and a slighter bruise upon her head. She got up, however, but was unable to stand upon the wounded limb. She was carried to bed, and the wound bandaged. On being brought, at a later period, to the *Hôtel Dieu*, the dressings were removed; and it was then seen that the patella was broken vertically into two unequal portions. The wound was suppurating and accompanied by great pain, extending over the whole limb. The general state of the patient was unsatisfactory. The tongue was foul, the skin hot and dry; she had much thirst, and some confusion of intellect, with insomniolence that refused to yield to powerful opiates. She had also frequent cough and expectoration. These complaints proved fatal.

A certain number of fractures of the same kind have lately been treated at the *Hôtel Dieu*. It is thus demonstrated that fractures of this kind, which have been passed over in silence in most works, and which have been altogether doubted by some writers, are nevertheless far from rare. But all these facts, at the same time, prove that this particular injury is always produced by direct force applied to the knee, and that it is generally accompanied by wound or bruising to a greater or less extent.

Diagnosis of Fractured Patella.—The diagnosis of fractures of the patella is generally easily established. When the bone is broken transversely, if the individual was previously standing, he falls to the ground and cannot get up; or if he makes the attempt, he immediately perceives that the limb has lost its power: he can only drag the broken limb while he rests upon the other. These symptoms prove the existence of fracture, but on examining the knee it is further found that

this is flattened; and on applying the finger over the patella, the space intervening between the fragments of the bone is easily perceived. The superior portion is dragged upwards by the muscles inserted into it, while the lower is retained in its position by the ligament which is attached to it. On raising the limb powerfully, so as to elevate it towards the pelvis, the muscles in front of the thigh are relaxed, and the separation of the fragments of the patella almost entirely disappears. If they be then rubbed against each other, crepitation becomes obvious; which puts an end to all doubt as to the nature of the lesion.

When the fracture is oblique, or longitudinal, it requires a more careful examination to detect it, in consequence of the smaller degree of separation which takes place between the fragments. However, in putting the limb in a semiflexed position, as practised by La Motte, the disunion of the fragments becomes more marked.

Treatment.—After what we have said, it will readily be perceived what the basis of our treatment ought to be. It consists in the application of means proper to remedy the accidents which accompany the fracture, and to effect the reunion with the greatest possible degree of exactness, of the divided portions. Absolute rest of the limb, general and topical bleeding, and emollients, generally suffice to accomplish the former purpose. As to the reunion of the fragments in the case of the transverse fracture, their separation being produced and constantly kept up by the action of the extensor muscles, the first indication is to neutralize this power, and to place the limb in a proper position: for this purpose I employ the following means. First, an inclined plane, formed of cushions placed one above the other, which ought to extend from the heel to the ischiatic tuberosity, and which has the double object in view of opposing the contraction of the flexor muscles, and of putting the extensor muscles in a state of complete relaxation, owing to the position which they give to the limb: secondly, two compresses, about twenty inches in length and four inches wide, made of thick strong stuff, which ought to be hemmed at the edges and extremities; the first is to be pierced with three apertures at one of its extremities, the edges of these apertures being also hemmed, while the other end is to be divided into three flaps. Thirdly, two bandages, three fingers' breadth wide, and from eight to ten yards in length. Fourthly, some graduated compresses.

The foot is first to be enveloped with some turns of the bandage; one of the long compresses is then to be laid on the

dorsal face of the foot; the whole is to be fixed with pins, and by means of two or three additional turns of the bandage. The compress is then to be stretched over the anterior face of the limb. This being done, the turns of the roller are continued, gradually winding it upwards, till it be just below the patella, from which point it is turned back parallel to the limb. Whilst an assistant now raises powerfully the muscles at the posterior part of the thigh, the surgeon surrounds this, at its middle part, with three turns of a second bandage, and then places the end of the second long compress on its anterior surface, where it is fixed by one or two further rounds, turning the extremity from above downwards. One or two more circular turns are made, and the bandaging then continued to the upper edge of the patella, what remains being expended upon the thigh. Graduated compresses are then placed above and below the patella, and the flaps of the one long compress passed into the apertures above-mentioned, and the fragments approximated by drawing the compresses in opposite directions and fixing their extremities, one on the leg and the other on the thigh. The limb is then placed on an inclined plane, the slope of which directs the foot towards the pelvis in such manner that the heel is much higher than the knee and thigh. By these means, which all concur producing and maintaining an exact contact between the fragments, a perfect reunion by bone may be effected.

In ordinary cases the junction takes place through intervening ligamentous substance. Sir Astley Cooper and other surgeons have carefully observed fractures of the patella and neck of the femur, and they have found a transparent fibrous or fibro-cartilaginous substance between the fragments. At the time this celebrated surgeon was at Paris (in 1829), I submitted to his examination some preparations in which direct union had taken place, and in which this fibro-cartilaginous formation was not perceptible. Doubtless this reunion is to be attributed to the long interval which had elapsed since the cure, the callus having thus had time to become ossified. Observe what happens in vertical fractures, and you will be convinced of the justice of this opinion. There, as there is no separation, the callus is always ossified in from six to twelve months. It is, therefore, the separation produced by the action of the muscles which opposes ossification; and when this tendency to drag the fragments asunder is neutralized, the transverse union is in all respects similar to the longitudinal.

Danger of tight-bandaging.—But how-

ever firm and well applied the apparatus may be, its action is constantly weakened by the yielding of its tissue and the action of the muscles. Besides, the pressure of the bandages often becomes insupportable, and sometimes even excites the most formidable mischief; an example of which occurred, some time ago, in one of the hospitals of Paris. A man, 43 years of age, fell upon his right knee and broke the patella. Next day the joint was considerably swollen, and very painful; nevertheless, an apparatus was applied similar to that above described. It was so tight, that in the evening the patient suffered extremely, and passed the night in great misery; but it was not till the end of forty-eight hours that his violent and continued complaints induced the surgeon to remove the apparatus. Patches of ecchymosis had already formed on different parts of the limb, and there were even some brown spots; notwithstanding which, the bandage was actually applied as tightly as before; but next day it became absolutely necessary to remove it. Gangrene took place on the sixth day after the accident; and the only hope of saving the patient's life was by sacrificing his limb. Amputation was performed, but he died next day, and the following are the appearances which presented themselves in the limb, sixteen days having intervened since the accident. The fracture was transverse; the fragments were separated about an inch, but still connected by the tendon of the extensors which had not been divided, and by small fibrous bands which ran from the one portion of bone to the other, and which proceeded from the interior of the patella, and not from its surface. At first these bridges were taken for new formations; but this idea was soon disproved, by comparing their resistance with the recentness of their supposed formation. The broken surface did not present any asperities, these having been removed by absorption. Between the two fragments there was a reddish substance, the consistence of which increased in proportion as it approached the fractured surface; at which point, indeed, it was almost cartilaginous.

The treatment of vertical fractures is to be conducted on the same principles as those which are not transverse. The limb is to be raised on pillows, the muscles relaxed, and the fragments kept in apposition. In this way the consolidation takes place in from sixty to eighty days. After this time, if the soft parts allow, the patient may be permitted to exercise the limb gently; taking the precaution to wear a knee-cap.

SURGICAL REPORTS

FROM THE

LONDON DISPENSARY.

By R. R. ROBINSON, Esq.

Surgeon to that Institution.

CASE I.—*Extensive Prolapsus Recti from debility, cured by tonic and astringent injections.*

JANE BIGG, æt. 72, admitted November 1st, a feeble old woman. Rectum protruded for the first time three weeks ago; it came down gradually, and has at times returned entirely. There is now a large portion (between two and three inches) of the rectum protruding, very red and villous, but not tender to the touch. Urgent tenesmus; difficult micturition; pain in the back; no appetite. After some little pressure the whole was returned through the sphincter. The rectum was so relaxed, that I am sure my whole hand might very easily have been passed into it.

Lot. Aluminis; Quin. Sulph. gr. j. ter die. Ol. Ricini, ʒss. p. r. n. Rest.

Nov. 2d.—Easier; bowel does not come down more than it did; urine passes quite freely; less pain in the back; has not kept her bed entirely as she was ordered to do.

Ordered to bed. Perstet.

5th.—Six motions from castor oil; rectum again came down on the third instant, from straining, and has kept down until this morning (not, however, to the same extent), when it went up, and is now entirely within the sphincter.—Perstet.

10th.—Much more comfortable; has kept her bed; rectum is now prolapsed only when she goes to stool. A piece of sponge soaked in the alum wash was introduced yesterday into the rectum; but it produced so much pain, that it could not be borne. Bowels open.

Rep. Mist.

12th.—Much stronger; quite easy; rectum does not prolapse.

Rep. Lot. Aluminis, et Quin. Sulph.

19th.—No return of prolapsus; quite comfortable.—Discharged cured.

CASE II.—*Prolapsus Recti, with Inflammation and Deposit of False Membrane, cured by antiphlogistic means.*

John Dyer, æt. 53, admitted October 23d, a feeble tremulous man, a long time melancholic. Subject to hemorrhoids; rectum prolapsed yesterday; has continued down ever since, and discharges a bloody

serum. The anus is now occupied by a large tumor, evidently the prolapsed mucous membrane of the rectum, some parts of which are of a bright vermilion colour, from numerous tortuous vessels; others are bluish, from veins shining through; parts are covered with flakes of lymph, of cauliflower-like excrescence, which adhered but slightly to the mucous membrane. The upper portion is dry, and of a deep grey colour, like the state of the fauces when the seat of diphtherite. The whole tumor exceedingly tender and painful; pain greatly increased on pressure; bloody serum continues to ooze from it; he has made numerous and several unsuccessful attempts to return it. Leeches have been applied with some relief.

Pil. Hyd. gr. iij.; Pulv. Ipecac., Pulv. Scilla, gr. j. o. n. Magn. Sulph. ʒss.; Ant. Tart. gr. ʒ, ter die. Rep. Hirud.

Oct. 25th.—Pain very great, preventing sleep. Leeches applied again; would not take; feverish; dysuria; the prolapsed part as great as ever; the mucous membrane highly vascular, covered with an organized false membrane firmly adherent; bowels open. Attempts were again made to return the part by means of sponge dipped in cold water; but though the tumor was diminished by these means, it was not altogether got rid of.

Rep. Mist. Lot. Plumb. ʒij.; ad. o. i. Tr. Opil. ʒi.

28th.—Tumor less; rather blacker; discharges serum; dysuria; no fever.

Cal. g. iij.; Opil. g. ss. h. s.; Rep. Mist. et Lot.

November 1st.—Dysuria increased; was much gripped by the calomel. Ten leeches were applied, and a bread and water poultice substituted for the lotion. He is reported to have lost nearly a quart of blood. The pain immediately subsided; the prolapsus has entirely disappeared; there are only a few piles visible around the anus. He micturates freely; no fever.—Rep.

5th.—Convalescent; feeble.

Inf. Gentianæ, c. ʒiss. ter die.

REMARKS.—In the two preceding cases we have illustrations of the same disease depending upon different causes, and requiring very different treatment. In the first the prolapsus appears to have been owing merely to local and general debility. There was an entire absence of pain and fever. The prolapsed mucous membrane did not appear in an unnatural state; but the whole rectum was exceedingly relaxed. The alum wash acted as an astringent on the prolapsed part; the

recumbent position assisted in preventing the descent when the membrane had been returned; the quinine improved the general health, and in nineteen days the cure was complete*.

In the second case, although there was general as well as partial debility, there was also much general and local irritation, which gave rise to subacute inflammation of the prolapsed mucous membrane; its vascularity was very great: it was quickly covered with a greyish false membrane, which also soon became organized and granular, and showed a tendency at one part to ulcerate, and at another to mortify. It was attended with very acute pain and much fever, and required the antiphlogistic treatment for its removal.

From the striking resemblance the appearance of this membrane had to the tensil, when affected with one form of inflammation, I was induced to try mercury, which, from its irritating the rectum, as it is apt to do, I was obliged to leave off. From the good effects of the large loss of blood, and the substitution of poultices for cold lotions, it does not seem necessary to resort to mercury to any great extent, except where the disease assumes a chronic form, and there is a tendency to deposition between the coats of the bowel, and then the Hydr. c. Creta. or Pil. Hydr. will be preferable to calomel.

Much as it is desirable to return the prolapsed part, as the sphincter acts as a ligature, and still further engorges the membrane, it will, I think, *generally* be found useless, and *always* very painful, to make the attempt in this form of the disease, until the inflammation and swelling have somewhat subsided, and then the part usually returns with facility of its own accord.

Two other cases of prolapsus recti occurred at the dispensary much about the same time as these; one in a boy, æt. 2½, who was cured in ten days by the alum-wash alone; the other was also in a boy, æt. 3, who had a short time previously been the subject of hooping-cough, by which his system had been much weakened; in this instance the membrane was slightly ulcerated; he was, however, entirely cured in three weeks by alum-wash, bark, and soda.

In these instances the prolapsus was chiefly, if not entirely, seated in the mucous membrane. In some cases, however, the other coats of the rectum have been likewise prolapsed.

* I have since learned that she has had no return.

LITERARY CURIOSITIES.

An ingenious contributor to our valued contemporary, the *Revue Médicale*, has endeavoured to lay down and illustrate certain rules or maxims to be followed by those who are much engaged in mental occupations. Among other topics which he has introduced, he alludes to the very different habits of different authors, when occupied in composition. Montaigne shut himself up in an old tower "*pour y digérer librement à loisir ses pensées.*" Rousseau herborized; it was, he used to say, "*en se meublant la tête de foin,*" that he could think most profoundly. Montesquieu composed the groundwork of the "*Esprit des Loix,*" while reclining in a post-chaise. Milton generally composed at night, sitting in his arm-chair, with his head resting on the back of it. Bossuet sat in a cold room, but kept his head warm with a quantity of coverings. Mr. Fox, after having indulged to excess in the pleasures of the table, would often, when he went home, retire to his study, and wrapping a cloth dipped in vinegar and cold water round his temples, sit engaged in study for ten hours successively. On the other hand, we are told that Schiller wrote most of his best pieces when he had his feet immersed in ice-cold water. Maturin, the author of *Bertram*, *Melmoth*, &c. withdrew into the most retired privacy when engaged in composition; when the inspiration seized him, he used to place a wafer between his eyebrows, to announce to his servants that they were not to disturb him. Jeremy Bentham was in the habit of writing all his ideas on small scraps of paper, and then stringing these together, so that they resembled rather a huge file of a merchant's bills, than the manuscript of an author's work. Napoleon, we are told by Bourrienne, when engaged in deep thought, would often be humming or singing a tune all the time, or notching the arm of his chair with the "*air d'un grand enfant;*" then suddenly he would start up, and point out the design of a monument to be built, or explain some of those mighty projects which used to astonish and terror-stricken the world. These, from out an almost infinite number of examples, sufficiently prove how different in different men are the circumstances favourable to mental labour. No general rule can be laid down; and the only advice to be suggested is, that each must work according to his fancy, habits, and ease.

What has been said of literary composers holds equally true of their musical brethren. Some, as Sarti, &c. can compose only in silence and gloom. Cimarosa delighted in noise and brilliancy. Sacchini

found relief, and almost assistance to his ideas, if several kittens were playing in the room beside him; and Paesielo, in his fits of composition, used to bury himself under the bed-clothes, trying to banish from his memory all the rules and precepts of his art, and giving vent to his feelings in the exclamation, "Holy Mother, grant me the grace to make me forget that I am a musician!"

It is an observation as old as the hills, that great and enduring works can be achieved only by patience and tedious thought. Perfection in any accomplishment, says Girodet, "ne s'improvise jamais." And Antoine de la Salle used to remark of any one commencing a work of importance, "celui n'est que l'ecolier de celui qui le finit." Even Voltaire, who perhaps of all authors had the greatest facility of rapid composition, was well aware of the requisite labour which must be spent in frequently revising his work; writing to M. Dargental on the occasion of a tragedy which he had very quickly composed, he wittily says, "Ma tragédie est finie, mais vous sentez bien qu'elle n'est pas faite. Mon ours de six jours demande six mois à être lèche."

But the tedious labour of long-continued and of often-repeated thought, is by no means the attribute of the authors of the present times; men of science, as well as men of literature, are in a mighty haste after fame and glory, and there is many an "esprit genereux," who, like Champollion, is feeding himself with the hope of leaving "sa carte de visite chez la posterité." Our ingenious contemporary concludes his amusing paper with some sensible remarks on what may be termed the "adjuvantia" of mental labour: having alluded to the advantages of an airy, cool, and quiet study, he then, *en passant*, suggests the propriety of wearing large, wide, and convenient articles of dress (every one knows "les Regrets à ma vieille Robe de Chambre," one of Diderot's best pieces), and points out the injurious effects of stooping too much, or for a great length of time, at a low table, when engaged in writing. It is well (says he) to rise from the table frequently to walk about the room, read aloud, and occasionally to vary the subject of meditation by one of a less grave character. These precepts, although seemingly trifling, are not so in reality. "An atom makes a shadow," was an observation of Pythagoras; and there is as much physiological as mere physical truth in the observation; the slightest organic lesion, the smallest injury, the least perceptible disturbance of health, may become, if neglected, the parent of much serious mischief*.

SYMPATHY BETWEEN TWINS WITH RESPECT TO DISEASES.

M. CAZENTRE, of Bourdeaux, relates the case of twin brothers, born in June 1829. They were sent out to nurse; and during the period of suckling they were not attacked with any severe disease; but it was observed with respect to slight indispositions connected with teething, that both were simultaneously and similarly affected. At the end of fifteen months they were sent home, from which time they were seen by M. Cazentre, who had thus an opportunity of witnessing what follows. In 1831 they both had quotidian fever, which in both began and ended on the same day; both had acute inflammation of the conjunctiva; both had colic, which lasted for twenty-four hours; both had two molar teeth at the same time. In 1832 they had each cutaneous affections and bronchitis simultaneously. In 1833 both had measles, and then scarlatina; in both the supereruptation and disappearance of the eruptions took place at the same moment. In 1834 they had whooping-cough; then ear-ache,—in either instance simultaneously. Very recently one was attacked in the evening with itching of the back of the neck, with an eruption of vesicles; early next morning the other had the same sensation in the same spot, and accompanied by similar vesicles.—*Gazette des Hôpitaux*.

POETICAL DESCRIPTION OF CHOLERA.

WE should have thought cholera about the last subject which any one would select for a poem; nevertheless, one of our brethren in France has detailed the whole history of the disease, symptoms, treatment, post-mortem appearances, and all in regular and flowing verses. As the production is a curiosity in medicine, we subjoin a specimen:—

"Voyez ce malheureux, courbé sur son baquet,
Les yeux caves, vitrés, s'épuiser en hoquet;
Cet autre, sans repos, pousser des cris terribles;
Sur lui-même tordu par des crampes horribles;
Ses muscles contractés d'un affreux tétanos,
Sur son lit ébranlé tout éraquer tous ses os.
De cette masse d'eau qu'il vient de boire tout,
Son rein ne reçoit pas, ne rend pas une goutte.
Et vous n'entendez pas, au pied du lit placé,
Un mot de cette voix dont le timbre est cassé.
Approchez, approchez, de cette bouche humaine
Recevez sur vos mains la haletante haleine.
Ah! que de ses poumons l'air qui s'échappe est
Froid;
Que sa langue est visqueuse et glace votre doigt!
Froissez donc cette peau de violet fardée
Et qui garde les plis dont vous l'avez ridée;
Et cherchez vainement dans ce poignet perclus
Une artère qui fuit, un pouls qui ne bat plus.
Tout en lui, tout est froid; chez ce mort qui respire,
La chaleur bienfaisante a perdu son empire,
Et quand il fait revivre un corps ainsi formé,
Dieu d'un souffle divin doit l'avoir animé."

* *Revue Médicale, and Med.-Chir. Review.*

GROWTH OF M. BROUSSAIS' "ORGANS."

SOME years ago, M. Broussais had his bust executed by an able sculptor, on which occasion, of course, an exact measurement of his several developments was made. The other day this celebrated original conceived the notion of having his head measured again, to ascertain if any change of his "organs" had been produced by the prodigious intellectual labours to which he had been devoted. The application of the craniometre shewed that the "metaphysical protuberance" had increased by three millimetres! This is no great matter, to be sure—but then in four years we could scarcely look for more. The *Journal de Phrenologie*, from which we borrow this curious fact (?), gravely explains the phenomenon by remarking, that since he has become a member of the *Academie des Sciences Morales et Politiques*, M. Broussais has not ceased to exercise his organs of logic and metaphysics !!!—*Gazette Medicale*.

lay nearly still and motionless; the fore-arms were laid across the abdomen, the wrists were bent, and the thumbs drawn into the hollow of the hand, and almost constantly trembling. Every now and then there was a paroxysm of apparently epileptic convulsions, and the patient seemed to recover his sensibility and consciousness for a time, but he soon relapsed into his former stupor.—On dissection, the attention of the physician was directed in an especial manner to the encephalic contents; and it was found that a tumor, of the size of a small walnut, had formed on the tuber annulare, and adhered to the outer surface of the cerebellum. This tumor was formed of naerous particles and layers, and belonged to that class of morbid deposits described by M. Cruveilhier as consisting of stearine and cholesterine; they appear to be quite inorganic, presenting no traces of vessels, or of cellular tissue.—*Archives G n rales*, and *Med. Chir. Rev.*

WESTMINSTER MEDICAL SOCIETY.

26TH SESSION, 1831-5.

Subjects proposed for Discussion.

CURIOUS DISTURBANCE OF THE MUSCULAR POWERS.

DISEASE OF THE CEREBELLUM.

A MIDDLE-AGED man was lately admitted into the H tel Dieu. The symptoms were feverishness, great debility, confusion of head, and inability to use his limbs, at least freely. There was no abdominal or pectoral distress. When he was put to bed, it was observed that the head was in a state of continual rotation, even when resting upon the pillow; it was not bent forwards or backwards, but only rolled about from side to side. The muscles of the face were occasionally convulsed, but the mouth was not distorted, nor was the tongue drawn either to the right or left side, although constantly moving with a tremulous agitation. The patient seemed to have a complete control over the flexors and extensors of the head; when assisted, he could raise himself up and sit in bed. The movements of the thoracic and abdominal muscles were healthy. The voluntary movements of the extremities were very imperfect; he could not raise his left arm at all to his head, and his right one only with considerable difficulty. The common sensibility was but little affected in any part; the intellect was confused; he could not answer many questions successively. In the course of a few days all the unfavourable symptoms were aggravated; the trembling oscillation of the head and tongue was incessant; the trunk and limbs

LECTURES

ON

DISEASES OF THE CHEST,

In the course of which the Application of
PERCUSSION AND AUSCULTATION
ARE FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE V.

THEORY OF THE SIGNS OF DISEASES OF THE LUNGS—(continued.)

AUSCULTATION.

THE subject to which I shall now call your attention is Auscultation.

Object.—What is the object of auscultation? To determine the specific lesions of structure either of the lungs or heart. We shall first speak of it merely in relation to the lungs.

Principles on which auscultation is founded.—What are the principles on which auscultation is founded? There are two: first, the lungs, during the acts of inspiration and expiration, produce certain sounds in the healthy and in most of their diseased states, which sounds are inaudible through the medium of the atmospheric air. The second principle is, that, as solid bodies have the power of conducting sounds better than the atmospheric air, so if a solid body be applied upon the parietes of the chest, those sounds can then be most distinctly heard.

Instruments employed.—Various solid bodies have been used for the purpose of auscultation. The first instrument was made by Laennec at the moment, and consisted of a quire of paper rolled tightly. It is a good conducting body, and would form a fair substitute on occasion for the ordinary stethoscope. The next form was

the stethoscope, also invented by Laennec. It consists of a cylinder of wood, a foot in length, and about an inch in diameter, perforated by a canal of four lines in breadth. It is hollowed out at one extremity into a funnel-like form, for the purpose of distinguishing delicate sounds. The funnel is fitted with an obturator, which added, the instrument may be used for the louder sounds, and for examining the movements, &c. of the heart. The stethoscope is divided into two parts, which may be united by this screw, merely for the convenience of carriage. Other forms have been invented, which are still more convenient. The instrument I commonly use is the one invented by Piorry. It is lighter than Laennec's, and answers the purpose equally well. You perceive that this is hollowed into a funnel-form at one end; an obturator is attached to it also, which is usually surmounted by the plessimeter. Sometimes an additional piece is fixed, for the purpose of lengthening it: this however is, I think, unnecessary. Be careful that you choose an instrument rounded at the extremity, to be applied to the chest; for they are often made sharp, and cause pain upon application.

Various materials have been used in constructing stethoscopes, as metals, cardboard; different kinds of wood, as ~~box~~ ^{hony}, box, &c. They are now almost universally made of cedar, which is perhaps the best.

Immediate auscultation.—Another instrument, and one which you have always the advantage of carrying about you, is the naked ear; and in most instances it is as good a stethoscope as you can employ. But there are some cases in which it is impossible to use the ear; as, for instance, at the humeral extremities of the clavicles, and in the axilla. Where the patient is a female, it is a matter too of delicacy to use intermediate auscultation in preference.

Position of the patient.—The objects you are to have in view in relation to the posi-

tion of your patient, is to place him in a situation convenient to yourself, and to render his muscles as tense as you can, by putting them upon the stretch. Thus, if you wish to examine anteriorly, you must place him in a chair; let him incline the head backwards, and throw his arms behind the chair; if laterally, then he should incline to one side, and place the arm of that side over the head, and you can then easily examine from the axilla downwards: if posteriorly, then the body must be bent forwards, and the arms firmly crossed in front.

Application of the stethoscope.—There are a few points also to be attended to in the application of the instrument. It should be held as you would hold a pen; facility must be acquired in holding it in either hand, and it must be applied firmly and steadily to the chest, otherwise a rustling noise is created, which often masks the sounds produced by the lungs. You should also apply it perpendicularly to the surface, and not at an angle; because, in the latter case, there will only be a single point of the instrument in contact, and not the whole circumference. Take care that you do not allow it to move backwards and forwards, for in doing so you create sounds which obscure those arising

from the lungs. It is also advisable, particularly in a thin person, to interpose something between the instrument and the chest itself. The shirt of the patient is generally sufficient; if not, you may employ a linen cloth or a little lint. Be careful, also, not to examine a patient in a silk dress; for silk also causes a rustling sound, which will deceive you. Stuff and flannel dresses are objectionable on the same account; they occasion noises very analogous to the “rhonchus crepitans;” and I have occasionally seen beginners diagnosticate softening tubercles beneath the clavicles, when the sounds have altogether depended upon the sort of dress worn by the patient, and the loose manner in which the auscultator has held the stethoscope. The extremity of the instrument, on which the obturator is fixed, should always be applied to the chest; the ear, of course, upon the opposite end.

We shall first consider auscultation in reference to the voice; secondly, to the respiratory murmur; thirdly, to the various sorts of wheezing or rhonchus heard in the chest; and, fourthly, in relation to certain sounds occasioned by diseases of the pleura. Perhaps the following tabular view of the sounds will assist your recollection:—

Auscultation of.....	The voice in..	Excavations	Pectoriloquy ..	{ Perfect. Imperfect. Doubtful.
		Trachea and larynx.		
		Bronchi	Bronchophony.	
	The respiratory murmur in	Pulmonary tissue ..	Puerile respiration.	
		Trachea and larynx.		
		Bronchi	Bronchial respiration.	
		Excavations	{ Cavernous respiration. Blowing respiration. Souffle voilé. Bourdonnement amphorique.	
	The rhonchus in	Bronchi	Rhonehus sibilans or sibilation.	
			Rhonehus sonorus, grave, or deep sonorous wheezing.	
		Pulmonary tissue ..	Rhonehus mucosus, or mucous rattle.	
	The sounds in diseases of the pleura		Rhonehus crepitans	{ humid. dry.
			Ægophony..	{ Simple. Combined with bronchophony.
			Metallic tinkling. Ascending and descending rubbing sound.	

AUSCULTATION OF THE VOICE.

We proceed to the study of the resonance of the voice:—1st, in tubercular

cavities or excavations formed in the lungs from any other cause; 2nd, in the trachea; 3rd, in the bronchial tubes; and, 4th, in the pulmonary tissue itself.

In considering the subject, we must revert to the principles of the instrument, and give some explanation of the theory of the voice. It is an experiment familiar to us all, that if a beam of wood be scratched at one end with a pin, the noise may most distinctly be heard by applying the ear at the other extremity of the beam, though you might not hear it at the same distance by the intermedium of the atmospheric air;—proving incontrovertibly that solid bodies convey sounds better than the air. I shall not enter into the theory of this, because it involves other questions with which we have nothing to do, but I state it as a matter of fact.

Let us now consider some points of the theory of the voice. The voice is produced in the act of expiration; the air then passes through a tube—the trachea—having at its superior part a moveable orifice, called the *rima glottidis*, an orifice which can contract and dilate, and consequently vary its diameter. The air, in passing through the *rima glottidis*, produces a sound varying in its gravity, according to the diameter of the opening: if the opening be contracted, it will be acute; if dilated, grave; and I take the liberty of calling this sound the primitive note, in the same way as I should call the sound produced at the embouchure of the flute, when the fingers are off the rest of the holes of that instrument, its primitive note.

The primitive note being thus produced, its sound passes outwards, but in its way becomes modified by the action of the muscles of the pharynx, the *velum pendulum palati*, the tongue, palate, lips, teeth, &c., to form words named guttural, lingual, labial, palatine, dental, &c. according to the parts which principally operate in producing the modification.

Pectoriloquy.—The words thus formed pass outwards to a distance proportionate to the force employed in forming the primitive note; but, as the trachea is always filled with air, and is in direct communication with the mouth, there is no reason why the words should not descend into that tube. If that be the case, and as solid bodies convey sounds better than atmospheric air, so a solid body applied to the trachea at the moment a person is speaking should convey the voice to the listener with greater intensity than the air at the distance of the length of the instrument used. Try the experiment, gentlemen, with each other—you will find it is so; nay, the voice is so completely conveyed through the stethoscope, that it entirely masks that from the mouth: it is true it is more hoarse, it is not so clear, but it is perfectly distinct: and this sound is the type of that which we shall here-

after describe under the name of *pectoriloquy*.

You may, however, readily suppose that for a tube to resound the voice it is necessary that it should be of a certain diameter: thus the largest reed of the instrument called the *paudean pipes* can be easily sounded; that facility diminishes as we ascend in the scale to the smaller ones; and, supposing these to diminish still farther until they became capillary tubes, no sounds could be elicited from them.

We have seen that the trachea resounds the voice; its two primitive divisions are of sufficient diameter to do so likewise; so that if the stethoscope be applied, in a thin person, upon the second or third dorsal vertebrae, the words can still be heard, although not so distinctly; but when these primitive bronchi split into smaller branches, which plunge into the substance of the lung, the resonance becomes less and less, and that even is effaced by the respiratory murmur; and when the tubes become capillary, no sound whatever is produced by them.

The consequence that may be drawn from these premises, is, that as the mass of the lungs consists of capillary bronchial tubes and air cells, the voice *should not* be heard at any point of the chest excepting at the second and third dorsal vertebrae of thin persons. Try the experiment, and you will find it as I have stated. We will now endeavour to explain the cause of *pectoriloquy*.

We shall hereafter have occasion to enter largely into the consideration of an adventitious deposit in the lung, called *tubercle*—the proximate cause of *phthisis*. *Tubercles* exist at first as isolated bodies, gradually increasing in size and numbers, until they unite and form solid masses; these masses soften, and are expectorated; but as they cannot be expectorated through capillary tubes, they burst into those of a larger calibre; and it follows of course, that as this softened matter becomes evacuated, it must leave a cavity proportionate in size to the quantity of the tubercular mass: if, then, a cavity be thus left, it follows also that we have now a space of sufficient diameter to resound the voice in a spot where it *could not* have been heard before. This resonance is called *pectoriloquy*.

All causes producing excavations of the lungs will occasion *pectoriloquy*—as gangrene, peripneumonic abscesses, &c.

As there are great variations in the size and form of cavities—as their parietes vary in consistence—as they are more or less near to the surface of the lung—so the *pectoriloquy* will be more or less complete. Thus *Lacine* has considered this sound

under the three heads of *perfect*, *imperfect*, and *doubtful*.

The pectoriloquy is *perfect* when the words are distinctly articulated through the stethoscope, and when the sign is exactly circumscribed to a spot.

The circumstances necessary to perfect pectoriloquy are, 1st, a cavity of moderate size: if the excavation be immense, as in this case [shewing a specimen], the voice is lost within it. 2dly, That the cavity should be empty. 3dly, That its parietes should be firm: thus, in this preparation, where you see the excavation is lined by a membrane of almost cartilaginous density, the pectoriloquy was complete. 4thly, That the bronchial opening should be sufficiently large. 5thly, That the excavation be near the surface. Even under these favourable circumstances, the phenomenon may be lost for a time, in consequence of a momentary obstruction of the communicating bronchial tube, from sputa: let the patient cough, the secretion will be removed, and the sign restored.

The pectoriloquy is *imperfect* when the voice is not distinctly articulated through the instrument.

The circumstances which cause this imperfection are, 1st, the cavity being multilocular; 2dly, its parietes being soft; 3dly, its incomplete evacuation; 4thly, its distance from the surface of the lung; and, finally, the smallness of the bronchial opening into it.

The pectoriloquy is *doubtful* when the voice is resounded feebly—when we cannot, except with difficulty, distinguish it from bronchophony. We must then bring to our aid the functional and general signs to form our judgment.

Voice in Trachea and Larynx.—The voice, as I before stated, in speaking of the theory of pectoriloquy, is perfectly articulated through the stethoscope when it passes from these organs.

Voice in Bronchial Tubes—Bronchophony.—The two primary bronchial divisions yield articulated sounds over the second and third dorsal vertebrae, in very thin persons. A very strong resonance is also often heard at the upper extremity of the sternum, from the presence of the trachea beneath it; and, as Laennec observes, you should be careful not to confound it with a doubtful pectoriloquy; but, in fact, it is often impossible to distinguish them.

The larger bronchial tubes, as they plunge into the substance of the lungs, produce no resonance; no doubt, because the air contained in the cells is an insufficient conductor of the sound. Thus we find that any cause tending to solidify the lung, so as to render it a better conductor, will allow the resonance of the voice in these vessels to be distinctly heard. These

causes are hepatization of the organ, extensive pulmonary apoplexy, and accumulation of tubercles. This sound has been called, by Laennec, *bronchophony*. It differs from pectoriloquy, inasmuch as the voice does not penetrate the instrument, nor is it heard articulated; its tone is different, and the sound is more diffused.

Voice in Pulmonary Tissue.—For the reasons I have before mentioned, the voice cannot be heard in the pulmonary tissue.

RESPIRATORY MURMUR.

The sounds produced by the passage of the air in inspiration and expiration, or the *respiratory murmur*, should be studied in the pulmonary tissue, the trachea, the bronchi, and in pulmonary excavations.

Respiratory Murmur in Pulmonary Tissue.—If you apply the stethoscope or the naked ear to the chest, particularly of a child of six or seven years of age, you will there hear distinctly, during expiration and inspiration, a perfectly soft murmur. It is impossible to convey by words the nature of sounds, for these are sensations that must be acquired by and for yourselves. I can only speak analogically, and say a sound is like this or that; for simple sensations admit of no definition. In the case under consideration, you hear a slight noise both in the act of expiration and inspiration—something like the soft murmur of a pair of bellows, in which the valve does not click. Laennec has well expressed it, by saying that it is like the sound produced by the occasional deep inspirations made by a person profoundly sleeping. Unless you obtain a knowledge of this normal sound, you will make no progress in auscultation. The respiratory murmur has nearly the same intensity over every part of the chest; however, it is less loud upon the scapulae and vertebrae, because of the intervening bones, and most distinct in the axilla, where there is the least mass of interposing muscles.

It is important here, as in percussion, to know whether the sounds are alike at all periods of life. They are not; for they are infinitely more audible in the earlier periods than in old age, and for the same reason I have mentioned before—namely, that digestion, nutrition, circulation, and consequently respiration, are more active in children than in grown persons. It is on this account that I recommend you to study the sound first in a child.

Differences also in the intensity of the respiratory murmur occur in persons of the same age: thus you will find in some it is very indistinct, in others very loud—so loud, that it is like that of a child, and has been consequently called *puerile* respiration. The latter particularly obtains in women, and in men of nervous tempera-

ments. This important consequence follows—that for the purpose of detecting disease, you should not compare the respiratory murmur of two individuals, but you should compare it in the different parts of the chest of the same person.

Some few practical points are necessary to attend to, in examining a person for this sound. In the first place, you should use the stethoscope without its obturator, and although the murmur may be heard through the clothes of the patient, yet the fewer they have on the better; indeed, if they be of silk, or certain sorts of stuffs, it is impossible to hear so delicate a sound at all. Sometimes, too, the patient is alarmed at the examination—especially if it be the first; they will suspend, interrupt, or precipitate their respiration: wait a few moments patiently—desire them to breathe naturally, without effort, and then you will commonly hear the murmur very well. If it be not distinct, tell them to make a deep inspiration, or sigh. I often find that the inspiration following a cough gives the murmur better, let that cough be voluntary or involuntary. Remember, however, that no act of volition on the part of the patient can increase the sound to the puerile character.

What are the inferences we are to draw from this respiratory murmur? Whenever it is heard in a given portion of the lung, you may be certain that there the organ is permeable to the air, and not diseased; but whenever it is not heard, you may be then as certain that the lung is impermeable, and diseased. The causes of the impermeability of the lungs to air, are various; it is impossible I can detail them now, as I should too much anticipate my subject; but the most common are hepatization, apoplexy of the lung, the accumulation of masses of crude tubercles, and effusions into the pleura, compressing the viscous.

It is important to observe, that whenever the respiratory murmur is absent to any considerable extent, the energy of the respiration increases in the healthy parts of the lungs, and the murmur there puts on the character of that of childhood, or it becomes *puerile*; and you draw the inference, that whenever the puerile respiration is heard, there is disease in some other part of the organ. This is a rule having but one exception, which we shall speak of in a future lecture.

Respiratory Murmur in Trachea and Bronchial Tubes.—If the stethoscope be applied to the trachea, or to the sides of the neck, a loud sound is heard during respiration; the same may be distinguished, although not with equal intensity, in thin persons, at the upper part of the sternum and at the root of the lungs; but when the bronchial tubes divide, and pass into the sub-

stance of the viscous, this sound is no longer to be heard, in consequence of the indifferent capacity of the air in the air cells to conduct it, and from its being masked also by the respiratory murmur of the pulmonary tissue.

Bronchial Respiration.—But when the portion of the lungs becomes solidified by hepatization, or by the presence of tubercles in masses, then, as no respiratory murmur is caused by the impermeable air cells, and as the solid organ is a better conductor of sound, the respiration is distinctly to be heard in the bronchial tubes; and of course the sounds are loudest where these vessels are nearest the surface. They are therefore of the greatest intensity at the root of the lungs and at the points corresponding to the upper lobes, at the anterior superior parts of the chest, and in the axillæ. This sound is called the *bronchial respiration*.

Respiration in excavations, or cavernous respiration.—The sounds produced by the respiration in cavities formed either by tubercles, peripneumonia, or gangrene, are very loud, and of the bronchial character; but they evidently give to the ear the feeling of a resonance in a capacity of much larger dimensions than that of any bronchial tube; these sounds may be considerably increased by desiring the patient to cough. Nothing can be more decisive of the presence of an excavation than the noises produced in this manner.

Blowing respiration.—This is a modification of the bronchial and cavernous respirations, in which, during inspiration, the patient seems to draw the air from the ear of the observer through the stethoscope, and blow it back again with force during expectoration. This takes place during quick respirations, or when the patient coughs or speaks.

The physical causes of this phenomenon are—1. The presence of an excavation, which approaches closely to the walls of the chest, in consequence of the thinness of the parietes of that excavation; this I have noticed frequently. 2. Laennec says that the same sound is produced from a large bronchial tube near the surface being surrounded by condensed substance, as when the lung is consolidated from peripneumonia, or compressed by pleuritic effusion. I am but little inclined to doubt Laennec's correctness, but I confess I have often sought for the sound from this cause, but hitherto without effect.

Souffle voilé.—Laennec also describes a modification of the blowing respiration, in which a moveable veil seems to be interposed between a pulmonary cavity and the ear of the auscultator. This is heard during coughing, speaking, or respiring.

The causes of the *souffle voilé* are, according to the same author—1. A superficial

cavity, with thin and supple parietes, not adhering to the costal pleura; so that whenever the patient speaks, coughs, or inspires, the loose and thin portion of the walls of the excavation flaps against the ribs. 2. A peripneumonic abscess, whose parietes are generally hepatized, but presenting here and there some points of engorgement; and 3. Where bronchophony is given by a large bronchial tube in peripneumony, part of the course of that tube having the lung between it and the ear of the examiner, in a healthy state, or only slightly engorged.

Bourdonnement amphorique.—Finally, you occasionally see an immense cavity, in which scarcely any of the lung is left, except a portion at the root, and a thin layer of its substance adhering to the costal pleura. Here pectoriloquy is lost; the cavity is too large to admit of it, but the respiration puts on a peculiar character. It is no longer a cavernous respiration, but something like the sound produced by blowing into a large empty bottle, or like the buzzing of a bee in a vase, whence Laennec has termed it *Bourdonnement amphorique*.

RHONCHUS.

We now proceed to the description of the various sounds known under the general appellation of Rhonchus.

Definition.—All noises which may be made during the respiratory act, produced by the air traversing fluids, or by a partial contraction of the aerian tubes; they accompany, and are rendered more evident by coughing. Such is the definition given by Laennec. There are various species of this sound.

Rhonchus sibilans, or whistling sound; its characters are various; it is sometimes a prolonged whistle, of divers tones; sometimes of very short duration, and like the chirruping of birds; it is occasionally similar to the clicking sound produced by the opening and shutting of a small valve.

Causes.—It appears to depend upon a small quantity of viscid tenacious mucus obstructing more or less the smaller bronchial ramifications, or from a swelling of the internal membrane of a bronchial branch of small or middle size; the first cause produces the clicking noise, and occasionally the sibilation, either of which may be made frequently to disappear by desiring the patient to cough, by which the obstructing mucus is dislodged. The prolonged whistle depends upon a thickened state of the mucous membrane.

Rhonchus sonorus gravis, or dry sonorous wheezing. The sound in this case is grave, and often very loud, frequently like that of snoring, or of the bass string of a violoncello when rubbed by the finger; it is often similar to the cooing of a dove.

Causes.—Laennec believes that this sound is occasioned by some change in the form of the bronchial tubes, as their compression by a tumor or engorged gland, or by a local and slight inflammation of the pulmonary tissue; or that it may be produced by the presence of very tenacious mucus; and finally, from a swelling of the mucous membrane at the commencement or opening of a bronchial tube, whereby its diameter is rendered smaller at its orifice than in the rest of its course. The two last causes are certainly the most common.

Rhonchus mucosus is a sound like that produced by the blowing of bubbles in a solution of soap and water. The ear can recognise most accurately the various sizes of these bullæ, and the tenacity of the mucosities in which they are formed. Their quantity and their situation in the lung can most easily be detected by a slight habitude; in fact, this sound is so very distinct, that I find it is usually the first that is determined by the student.

Causes.—The rhonchus mucosus is produced by the air passing through fluids accumulated in the trachea or bronchi, or through purulent or softened tubercular matter. Thus it occurs in catarrhs, where the secretion is considerable, or in hæmoptysis, when blood obstructs the air passages; it exists also in tubercular excavations, containing a certain quantity of mucus or softened tubercular matter; it is found also in gangrenous or peripneumonic abscesses, when they burst into one or more bronchial tubes, so that the air communicates freely with their cavities; but in these three last cases this sound is modified in its character; the bullæ are larger; they are evidently contained in a more circumscribed space; a cough, or a forced inspiration, conveys to the ear the sensation of the rhonchus being formed in an excavation in the lung. The loudness of the rhonchus mucosus, and the largeness of the bullæ, would then, perhaps, be better expressed by the term gurgling than any other, a term equivalent to the “gargouillement” of Laennec.

This gurgling sound is occasionally distinguished by the patient himself, and he will point to the situation of the cavity as being the part of the lung from whence the expectoration proceeds; this is, however, somewhat rare, but I have met with it. Laennec describes instances in which the pulsation of the subclavian artery produced a slight mucous rattle, from the vessel striking the parietes of the excavation. This is certainly a very rare circumstance; I cannot say I have observed it.

This rhonchus may, although very seldom indeed, be heard at a distance from the chest, or, which is more frequent, be felt by its communicating its vibrations to the hand; thus, as in this preparation [shew-

ing it] the tubercular matter found its way through the parietes of the chest, formed a tumor which, as you perceive, has burst externally; this tumor gave upon pressure a gurgling sound. A second case mentioned by Laennec is, where a tubercular excavation bursts through the pleura, whose two laminæ have been previously united by an abundant cellular tissue, yet sufficiently loose to allow of the infiltration of air and pus within it. A third case, is of an extensive multilocular cavity, half full of pus or softened tubercular matter; this also occasionally produces a rhonchus sensible to the hand. He had not sufficiently verified this sign. I have no hesitation in saying, that I have distinguished it now frequently.

The intensity of the mucous rattle varies, of course, according to the quantity of fluid which the air traverses, according to the force with which a patient is made to respire or cough, and the distance at which the accumulated secretion is placed from the ear of the observer, so that the sound may be *distinct* or *obscure*; these differences are very easily determinable by practice.

Rhonchus crepitans.—There are two varieties of this sound, the one described by Laennec as the humid crepitation, the other as the dry.

The humid crepitation.—This is very analogous to the sound produced by the crepitation of salt exposed to a moderate heat, or to that made by the insuflation of a dried bladder, or still more to the sensation given to the hand when compressing a healthy lung; it carries with it also a distinct feeling of humidity.

Causes.—Whenever air and fluid coexist in the ærian cells, humid crepitation may be heard; thus it is the pathognomonic sign of the first stage of peripneumonia, or inflammatory engorgement of the lung. It is very distinct when that organ becomes œdematous; it is also occasionally found in hæmoptysis. It is a sound of great practical importance, and deserves your fullest attention.

The dry crepitation, or crackling sound, is heard principally during inspiration. This sound communicates to the ear the sensation of dryness and unequal dilatation of the pulmonary cells; it is very like the noise produced by blowing into a dried bladder, and the bullæ of the crepitations are much larger than in the preceding species.

Causes.—The dry crepitation is the pathognomonic sign of vesicular and interlobular emphysema of the lungs, particularly the latter.

ŒGOPHONY.

This sound may be easily confounded

with pectoriloquy and bronchophony, and consequently requires the greatest attention on the part of the student.

Laennec gives the following description of its characters:—Simple œgophony consists in a particular resonance of the voice, accompanying or following the articulation of the words. The voice appears more acute and silvery, and trembles upon the surface of the lung; it is rather like an echo, repeating the words and final sounds, than the voice itself. It is rarely introduced into the tube of the stethoscope, and still less frequently traverses it completely. It has another constant character; it is trembling and saccaded, like that of a goat, and its tone is very similar to that animal's. When the œgophony occurs near a large bronchial tube, particularly at the root of the lungs, then a bronchophony more or less marked is generally superadded; and this combination gives rise to various modifications of sound. Thus it may be like the voice transmitted through a metallic speaking trumpet, or a broken reed, or a comb, or like a person speaking with a piece of money placed between the teeth and lips; and, finally, it is often exactly similar to that of the personage familiar to us under the denomination of Punch.

To hear this sound distinctly, the stethoscope should be applied firmly upon the parietes of the chest, and the ear lightly upon the instrument.

Causes.—It exists only in those cases in which there is a slight effusion into the chest, either from an attack of acute or chronic pleurisy, or hydro-thorax; and in proportion as the effusion increases, the œgophony disappears; as the fluid is absorbed or evacuated, the sign comes on again, evincing that it depends upon the presence of a thin layer of fluid between the pleuræ.

The œgophony is never heard in a single point, like the pectoriloquy, but is always more diffused; thus it is commonly heard between the base of the scapula and the corresponding part of the vertebral column, in the whole contour of the inferior angle of that bone, and in a zone of three fingers' breadth, extending from the middle of the scapula to the nipple. Occasionally, however, the sound may be heard all over the side affected; it then evidently depends upon adhesions between the two pleuræ, preventing the lungs receding from the ribs, adhesions which admit, nevertheless, of an insinuation of fluid sufficient to produce the phenomenon.

Œgophony seems, then, to depend upon the natural resonance of the voice in the bronchi, transmitted by the intermedium of a thin and trembling layer of effused fluid, and rendered more sensible by the

compression of the pulmonary tissue, by which that tissue becomes a better conductor of sound.

It is at the upper portion, or edge of the layer of fluid, that the ægophony is most distinct: thus the extent of the sound above described supposes the patient to be seated; but if he be placed on the face, then the fluid will gravitate towards the sternum, and the sign will almost entirely disappear from the space between the base of the scapula and the vertebral column, and will be heard at the side only, and in a direction transverse to the ribs. It will be found, too, that as the absorption of the fluid continues, the ægophony leaves the upper part of the chest, and is heard lower down, following evidently the course of the fluid.

The ægophony may be always considered as a favourable sign, because it proves that the effusion of fluid is but slight: its persistence many days, and after the acute period of the disease, demonstrates that it does not increase in quantity, and, generally speaking, shows us that the affection will not become chronic.

The ægophony, like pectoriloquy, may be sometimes suspended, when the bronchial tubes are obstructed by accumulated secretions, preventing the voice descending through them; but, as catarrh does not very commonly co-exist with pleurisy, the sign rarely ceases suddenly.

The argentine and trembling tones of ægophony are generally most perfect at the anterior and lateral parts of the chest; for when the phenomenon occurs between the base of the scapula and the vertebral column, it is almost always joined with the natural bronchophony, in consequence of the bronchial tubes being there of a larger size. It is in the latter part that the voice occasionally completely traverses the stethoscope.

Ægophony and bronchophony are combined in cases of pleuro-peripneumonia.

Ægophony, bronchophony, and pectoriloquy, may be all united in cases of pleuro-peripneumonia, combined with abscess of the lung.

The theory of ægophonism is not yet well understood: in all probability it depends upon a partial flattening of the bronchial tubes by the compression of the effused fluid, and that the voice is modified in passing through them in that state, and subsequently in passing through the secretion itself.

METALLIC TINKLING.

Laennec so denominates this sound from its analogy to that produced by slightly striking with a pin a cup of metal, glass, or porcelain, or by dropping a few grains of sand into such ves-

sels. The sound is heard during respiration, coughing, or speaking; the sound is feeblest, however, during respiration, loudest when the patient coughs: it sometimes happens that it is heard only during the respiratory act, and not at all while coughing or speaking; but this is a rare circumstance.

Causes.—The metallic tinkling is caused by the resonance of the air, agitated upon the surface of a liquid contained in a preternatural cavity formed within the chest. It occurs, therefore, in two cases:—1. In pneumo-thorax, combined with effusion. 2. In a large tubercular excavation, containing a certain quantity of very liquid pus.

In cases of pneumo-thorax, combined with effusion of the cavity in the pleura, Laennec asserts that it is necessary for the production of the metallic tinkling that there should exist a fistulous communication between the pleura and bronchi, such as occurs in tubercular or peripneumonic abscesses, or from gangrenous eschars opening at once into both: that it constantly happens under these circumstances, and in the greatest perfection, is incontestible; but that such a communication is essentially necessary I doubt, inasmuch as I have, in a great many cases in which the metallic sound was most distinct, endeavoured to discover, post-mortem, a fistulous orifice without success. We shall revert to this subject when we arrive at the description of the specific diseases of the lungs, in which this sign may be heard.

FROTTEMENT ASCENDANT AND DESCENDANT.

These are sounds so called by Laennec from their causing, during inspiration and expiration, a sensation to the ear as if a bone were rubbed by the finger, and heard through the stethoscope, giving the feeling of substances ascending and descending, and rubbing against each other with a certain degree of roughness. The same kind of sensation is also distinguishable by the hand, but infinitely more obscurely.

Causes.—This phenomenon depends, at least in the greatest number of cases, upon interlobular emphysema of the lungs, and is combined with the dry crepitating rhonchus. It is supposed, also, that the same sound might be produced by the projection of osseous, cartilaginous, tubercular, or scirrhous deposits, from the surface of the lungs or pleura; but this has not yet been proved.

[In page 67, in the paragraph above that contained within the brackets, the word "*left*" should be "*right*," and the word "*right*" should be "*left*."]]

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY PROFESSOR MAYO, F.R.S. &c.

II.—On Hypertrophy and Atrophy of Bone.

I.—**HYPERTROPHY** is the abnormal increase of a part, without inflammation or change of structure. Bones are liable to partial and to general hypertrophy—that is to say, the abnormal enlargement may affect a portion or the whole of a bone: the latter case, however, is rarely met with.

Hypertrophy of bone hardly constitutes *disease*; or if the more serious cases deserve that name, the transition from health to disease is, on this occasion, extremely gradual, and made by insensible steps. It is a principle, which reigns in the animal economy during health, that exercising a part strengthens it. Parts of which the action is *mechanical*, become thus *mechanically* strengthened. The arm of a blacksmith acquires, through daily exertion, additional muscular force, *weight*, and *size*: the bones in it enlarge; their crust becomes harder and of a compacter grain; and the lines upon the surface, which give attachment to tendons, become rough and prominent ridges: this is health.

In Mr. Cheshire's apparatus for weakness of the spine, the weight of the head and trunk is thrown upon the haunch-bones and the chin. A segment of a steel hoop rests upon the ossa ilii, from the middle of which a rod rises vertically behind the spine, higher than the head, over which it arches, terminating in a hook: a strap passing beneath the chin of the patient is suspended to the hook. In those with whom this instrument has been used, the lower jaw, having to sustain unusual pressure, has often enlarged, throwing out a bony swelling at the part where the chin-strap tells. This swelling might be classed as a *disease*: yet it evidently results from no other physical cause than the salutary law of growth, that a part is strengthened in proportion to the exertion imposed upon it: agreeably with that law, when, on discontinuing the use of the instrument, the call for increased strength in the jaw ceases, the bony swelling disappears.

Such a swelling upon a bone—an instance of partial hypertrophy—is called an *exostosis*.

Perhaps nothing is more wonderful in physiology than the correctness with which the proper size, and shape, and outline, of the different parts of the body, is maintained during infancy and childhood, while growth is in rapid progress, and the constituents of the frame are perpetually

changing. It is all the less surprising that during this period one or other of the bones should sometimes grow out abnormally. This incident produces another instance of exostosis. The clavicle is one of the bones the most subject to it. The disorder requires no treatment: it is almost sure to disappear after a year or two; either the rest of the bone *grows up* to the enlarged surface, or the superfluous part is absorbed, and not replaced in the next substitution of new bone.

Exostoses, however, are more frequent when the body has recently attained its full growth. Nor is it difficult to imagine why this should be. But the disease is not limited to the early or middle periods of life. A patient, about sixty years of age, who was under my care in the Middlesex Hospital, had an exostosis of the first rib, which threw forward the subclavian artery so as to present the appearance of subclavian aneurism. He had not observed the swelling till some months before he applied for advice.

The causes of exostoses, as of other enlargements, cannot generally be traced: it is, however, certain that they are occasionally produced by mechanical causes,—by pressure, or by a blow. The most frequent seats of this affection are the upper part of the humerus, the upper part of the tibia, the lower portion of the femur. The adjoined figure (fig. 1) represents an exostosis in the last-named situation. The shape of exostoses varies with the kind of bone upon which they grow. In the long bones they are generally narrow, and of greater height than thickness; sometimes largest at their base, in other instances the reverse. In the flat bones they are commonly broad, with no great elevation; in the round bones, rounded or nodular. To this law, however, there are many exceptions.

Exostoses being in their nature healthy bone, present in their structure all the varieties which healthy bone exhibits. Sometimes their grain is dense and compact: this is especially the case when they grow from the cranial bones—as upon the temple, or into the orbit. At other times they present a crust of variable thickness, and an internal cancellous structure of greater or less closeness and regularity of lamellation. The adjoined figure (fig. 2) represents a section of the natural size of the exostosis before represented. It has a thin cortex and a light cancellous structure. The cortex of the original bone appears partly to have remained in its original plane—partly to have been lifted with, and to have formed the crust of, the exostosis.

Exostoses have not more sensibility than healthy bone: but they are susceptible of inflammation, and then become the seat of

FIG. 1.

FIG. 2.

pain; and they often occasion pain by their pressure upon more sensible parts. Upon the same principle, when in the neighbourhood of important organs, they are liable to disturb their functions. Fixed local pain in the head, and epilepsy, have been produced by the growth of spines from the inner surface of the cranium.

Sometimes the tumor which forms an exostosis is not originally bony. A child, six months old, had a soft tumor growing from the front of the alveolar process of the upper jaw. Sir Astley Cooper removed it by an operation, but it grew again, and became hard. The subject of

this disease grew up a fine young woman in every respect, but for the tumor of the jaw, which for a time grew with her growth. At the age of 19, when I was consulted, the tumor produced great deformity. It projected an inch and a half beyond the under lip, and pressed the upper lip, which adhered to it, to the nose. Its length was $2\frac{1}{2}$ inches; breadth, 2; height, $1\frac{1}{2}$. The tumor was now an exostosis of cancellated, but extremely hard bone. It had not enlarged during the preceding five years. With Sir Astley Cooper's advice, and in his presence, I removed it. It is nearly three years since the operation was performed. The tumor has not returned.

The principles to which a surgeon looks in the treatment of exostoses are the following:—

Time may do something. In the common course of nutrition,—of removal and substitution,—exostoses may disappear spontaneously.

The nutrition of an exostosis may be disturbed by exciting increased action in adjacent parts. Upon this principle the tumor is sometimes dispersed by blisters, issues, or setons, applied in its vicinity.

There are medicines (the action of which is indeed imperfectly understood), that modify the growth of parts, and affect the nutritive processes in bone especially; these are mercury and iodine. They are sometimes useful in exostosis, and may be tried, if not contra-indicated by particular circumstances.

Finally, an exostosis may be removed by an operation, the base of the tumor being sawn through, or cut with a chisel or forceps. After this an exostosis does not commonly return. There was a young woman, a patient in the Middlesex Hospital, who suffered severe pain from an humeral exostosis, which Mr. Cartwright removed after trying many remedies for its relief. In a year the exostosis returned. A rubefacient plaister was now applied round the arm, when an abscess formed near the second exostosis, and it disappeared.

Exostoses sometimes perish suddenly by necrosis.

There is a preparation in the King's College museum of a tibia and fibula greatly enlarged, but not appearing to have been inflamed. The structure of the bones appears healthy. The person of whom I purchased this specimen assured me that the bones were from a Barbadoes leg. It is certainly not unlikely that such a state of the bones should occur in that disease.

A patient died in the Middlesex Hospital, who had been affected with epilepsy. The convolutions of the brain were remarkably flattened. On examining the cranium, the inner table of the frontal, parietal, and occipital bones, appeared hypertrophied; *all the arterial grooves were of unusual depth.* The bones were not particularly vascular, nor bore, I thought, the appearance of having been inflamed.

A sort of hypertrophy of bone is its extension into the ligaments and muscles. In one of our preparations, the femur is fixed immovably in the acetabulum by ossification of the anterior part of the capsular ligament, and of part of the iliacus internus. Mr. Langstaff, in his rich pathological museum, has a beautiful specimen of ossification, which appears to have spread from the femur, and involves the vastus internus, the fibrous structure of which is converted into bone.

The alliance between the ossification of ligament, muscle, and tendon, and exostosis, (or at all events the origin of the former from the bones), appears to me well established by the remarkable skeleton, called Mr. Jeff's, in the Hunterian museum, of which the following is Mr. Owen's excellent account:—

"It is the skeleton of a man, 39 years of age, and is remarkable for the production of ossific growths from many parts, of vari-

ous dimensions and extent—some forming exostoses merely, whilst others pass from one part of the skeleton to another, and have thus produced ankylosis, or immobility of most of the members. The exostoses may be observed on the os frontis, mastoid process, and occiput, and in other parts of the skeleton where muscles are attached, as near the angle of the lower jaw, where the masseter is inserted, at the extremities of the spines of the vertebræ, at the coronoid processes of the ulnæ, in the femur, at the part where the gluteus maximus is implanted.

"The second and more extensive kind of ossifications have in general followed the course of the larger muscles, and may be seen, on the right side, in the situation of the deltoid, joining the clavicle and acromion of the scapula to the humerus, in the situation of the supraspinatus, and passing from the inferior angle of the scapula to the humerus, in the situation of the teres major and latissimus dorsi. On the back, more extensive ossifications of the muscles appear, which affix the scapulæ on both sides to the sacrum and ilium, and to the spines of the lumbar and dorsal vertebræ. On the left scapula, the ossification of the teres major has not extended quite to the humerus; but the dorsum presents a singular process or ossification, with smooth sides, and a flattened overhanging margin, like an auxiliary or second spine.

"From the pelvis, ossifications extend from the sacrum and ilium in the direction of the gluteus magnus, and from the tuber ischii and os pubis in the course of the biceps and triceps abductor muscles: these extend to the right femur. Ossifications of the tendinous and ligamentous parts are still more common, producing ankylosis of the vertebræ, of the left elbow-joint, of the tibia and fibula to each other on both sides of the ankle-joint, and general consolidation of the bones of the tarsi."

II. *Atrophy* is degeneration of growth, deficiency in the size and weight of a part, and commonly of one or more of its usual constituents in particular. Atrophy in bone is attended with deficiency of bone-earth, or more correctly of the *proper osseous tissue*.

I amputated the leg of a young woman for disease of the tibia, which had existed eleven years. At its commencement it had attacked the head of the bone, and implicated the knee-joint, which became ankylosed. The disease then left the knee, but continued in the middle and lower part of the tibia; the patient could not use the limb, and it wasted where it was not diseased. One of the most remarkable features in the preparation from this case, which is

preserved in our museum, is the atrophy of the upper portion of the limb. The head of the tibia is a thin shell of bone; and instead of its proper close cancellous structure, a few fine bony threads alone are drawn across it. Among these the marrow lay in large masses, semifluid, supported by the medullary membrane alone.

In childhood, and particularly in young females, the round bones are liable to a form of atrophy, which corrects itself with advancing years. The weakness involves the ligamentous structures. It shews itself at the ankles, at the knees, but principally in the back; the spine becomes curved from weakness, giving first at the loins, but at the same time bending above in the opposite direction, to preserve the perpendicular; the curvature is sometimes forward. This complaint is atrophy from arrest of structural growth, and is to be treated on principles purely physiological.

In old age the bones become weaker and more brittle. The cortex is thinner; and in it, and in the cancelli, the proportion of osseous tissue is diminished. This is the cause of the frequent fracture of the neck of the femur in elderly persons. The mechanical disadvantage of the obliquity of the part now becomes apparent. In its progressive degeneration of structure, the neck of the femur is even, when not broken, depressed and shortened.

Sometimes in middle life the bones are unusually brittle. A stout-looking man was a patient in the Middlesex Hospital, in 1818, under one of the physicians, with some trifling ailment: he was cutting a slice of bread, when his humerus broke. I happened to have the care of it; it united as readily as another bone; and this is observed in general of atrophied bones, except in extreme cases, or where a morbid structure additionally exists in the bone,—or where the system is scorbutic, or tainted with lues, or loaded with mercury; (which causes are likewise said to produce fragility of the bones.)

In persons affected with carcinoma of the breast, the ribs are commonly found atrophied, so that they may be readily cut with a knife. Their cortex is very thin, and the osseous plates and threads of the cancellous structure are thinner and fewer than natural. The cells contain a reddish-brown and slightly-gelatinous fluid. The bones of the extremities are likewise often unusually brittle: sometimes, but very rarely, carcinomatous tumors are found in these brittle bones; of this there is a specimen in our museum. But generally nothing is to be observed in the brittle long bones of persons who have died of schirrhus. A patient in the cancer ward of the Middlesex Hospital, for carcinoma of the breast, broke her arm in raising herself in bed. Not many weeks after

this she died. I carefully examined the bone, but to the eye, and when cut through with the saw, it seemed as compact and hard as healthy bone.

In the College of Surgeons there is a specimen of an *adult* humerus, of which the crust is as thin as a wafer, and the interior looks as if filled with tallow; towards the lower part, for about two inches above the condyles, the bone appears to be a vascular sac of membrane. Mr. Hunter considered this to be *mollities ossium*. In the museum of the London Hospital are specimens from the body of a woman who died at the age of 72, which very much resemble that which I have referred to. She had been confined to her bed for four years with paralysis of the lower extremities: the hip and knee-joints had been for a considerable time permanently fixed; her appetite was always good. A month before her death, on making a slight exertion, the right thigh-bone broke, and shortly after the right arm. Mr. Hamilton, with very great liberality, has given to the King's College museum a preparation of one of the bones from this body; and the following is his account of the general post-mortem appearances.

"The lungs were healthy; the heart rather large and soft; the abdominal viscera and mesenteric glands healthy; there was considerable calcareous deposit in the lumbar and iliac glands. In the cranium, when the dura mater was opened, three or four ounces of fluid escaped, and there were some small tubercles attached to its under surface; the substance of the liver was natural; the articulations were in a healthy state; the periosteum covering the bones generally appeared natural, but over the trochanters it was entirely detached; the bones of the cranium and pelvis could be cut with a knife, while the ribs and vertebrae were but slightly affected, and scarcely less firm than usual; the bones of the lower extremities were far more extensively diseased than those of the upper; the thigh-bones consisted of a mere shell of bone filled with a fatty substance; the fractured extremities of the femur and humerus had a slight ligamentous connexion."

In Mr. Wilson's description of a case of *mollities ossium*, in a woman who died at 48 years of age, the only bones which were not entirely softened were the sacrum and the bones of the feet. The bones consisted of a thin, flexible, and brittle shell; and in the place of cancelli, a substance resembling coagulated blood was found, with cells in it containing oil.

The weakness of the spine in young females, which I have already adverted to, is perhaps the slightest form of a disease, which, when aggravated, produces the

most serious deformity—this is *rachitis*, or *rickets*. The disease is a softening of the bones, which commonly shews itself in early childhood, but may make its appearance at any time before puberty. In the worst cases, the spine becomes curved in various directions, the sternum projected, the ribs depressed and twisted, the sacrum pressed towards the pubes; the clavicles become more bent and prominent forward; the os humeri is distorted outwards; the lower ends of the radius and ulna are twisted in the same direction; the thighs are curved forwards or outwards; the knees fall inwards; the spine of the tibia becomes convex; and the feet are thrown outwards: that is to say, the trunk and limbs become bent in directions determined by the action of the muscles, and by the weight and pressure which they have to sustain.

The flexibility of the bones is produced by deficiency of the proper osseous tissue. The crust of the bones becomes extremely thin, and the osseous cancelli nearly disappear. The bones are lighter, and may be cut with a knife; they present throughout a spongy or cellular tissue. Mr. Stanley observes, that “the consistence of ricketty bones which he has examined is nearly that of common cartilage, and that they present throughout an arcolated texture; the cells are in some parts large, and contain a brownish gelatinous substance*.” Mr. Stanley remarks, that he has never noticed any expansion in the articular ends of ricketty bones.

There is a natural period to this disease: as the body reaches its full growth, sooner or later the atrophy ceases, and the bones become set in the deformity to which they were compressed when in their softened state. The formation of bone is now often carried to excess: strong ridges are formed in the concavities of the curvatures of the long bones, and the edges of the vertebræ enlarge and encroach upon the intervening ligaments. In one remarkable specimen in our museum of rachitic curvature forwards of the spine, eight adjoining vertebræ are by the extension of ossification ankylosed and converted into one bone. Mr. Stanley has pointed out that there is method in this abnormal growth, and that the superabundant bone is placed exactly where the rachitic curvatures of the skeleton render it mechanically weaker.

Preternatural brittleness and flexibility of bones are the result of different degrees of the same cause. Moderate atrophy produces brittleness; a greater degree, flexibility with greater brittleness.

CURE OF SUBCUTANEOUS NÆVUS, BY THE SETON.

To the Editor of the Medical Gazette.

SIR,

ABOUT the year 1830, a short paper, on the “Cure of Subcutaneous Nævus, by the Seton,” was published by me in the North of England Medical and Surgical Journal; and as it was then doubted by some, who were polite enough to notice that paper, whether so apparently simple a remedy was adequate to the removal of these growths, I read with pleasure the communication of Mr. Macilwain on the same subject, which appeared in the last volume of the Medico-Chirurgical Transactions of London. Some degree of discrepancy, however, exists in the result of the seton in our respective cases; for, while in mine it was not required to be continued beyond six or eight weeks, in Mr. M.’s the plan was extended to a period of nearly six months. This would seem to be owing to two circumstances; namely, the small proportionate size of the seton employed by that gentleman, and his having depended solely on this measure.

In the cases which I have already given to the public the effects of the plan were expedited by the addition of some irritating application to the channel of the seton, which seemed to be necessary, especially in the two latter instances, to produce, within a moderate period, the requisite amount of inflammation. On these occasions the nitrate of silver and sulphate of copper were used; but in cases which have occurred to me subsequently, the potassa fusa, as more certain in its influence, was substituted with the happiest result.

The rule originally propounded to guide us in the application of the seton ran as follows:—“In employing the seton it is necessary to secure two material objects; the suppression of hæmorrhage from the vessels divided by the needle, and, subsequently, a degree of irritation sufficient to excite inflammation and suppuration throughout the diseased mass. The first may be accomplished by having the skein of thread large enough fully to occupy the apertures made by the needle; and the second, by using a needle that will admit, relatively to the dimensions of the tumor,

* Medico-Chirurgical Transactions, vol. vii.

a seton of considerable proportions. If, however, the irritation fall short of the proposed objects, easy means are afforded, by the newly-established channel, of applying other irritants, or even caustic, to the residue of the morbid growth, without destroying the integument, which in Letlow's case, it will be seen, was required, and answered the best expectations*."

By the way, Mr. Macilwain observes, that the *first* of my published cases was dated subsequently to the period when the seton was suggested to his mind, and practised in the case he has reported; but if he would take the trouble again to refer, he will find that the date even of my *last* anticipates by, at least, *two years* the first he has related.

The example noticed by Mr. Lawrence, in a clinical lecture delivered two or three years ago, did not appear to me to be one to which the plan in question was at all adapted; and, therefore, his failure in that instance by no means negatives the utility of the seton as employed under particular circumstances; nor did he, in my humble judgment, persevere sufficiently to bring about a successful issue, even had the case been judiciously selected. At the time I read the lecture my impression was, that his mind was too strongly imbued with the idea that the vascular structure of nævus was so unsusceptible of inflammatory action, that no ordinary means were competent to light it up in a sufficient degree to accomplish the effect intended. The cases recently brought before the public, as well as those which preceded them, do, I hope, shew satisfactorily that this opinion is not, at least to the full extent of his remarks, correctly founded.

The circumstances which claim a preference for the seton, as I think, are developed in the following paragraph:—

"I would not be understood to suppose that the seton commands the preference in every case, or is intended to supersede the other means recommended for its cure. It is only under particular conditions that I should even advocate its adoption; for it is, comparatively speaking, tedious; and, on the whole, not less painful, perhaps, than the plans at present in use. Two principal cir-

cumstances weigh with me in choosing the seton; namely, the magnitude and situation of the tumor. If the size of the nævus be such as to preclude the employment of the knife, caustic, or ligature, then I am of opinion that the seton may be adopted with greater certainty of success than the tying of the arterial trunk which supplies the part to which the tumor is attached, as in the two first examples related, which would admit only of one of these alternatives. Then, again, as to situation: if it should be an object to save deformity, which undoubtedly it is, the seton would appear to be admissible in those venous subcutaneous growths which affect the head or face, or such parts as are liable to be left uncovered by the dress, especially in females, unless such growths, from their small dimensions, allow of removal by the knife, so as to leave a more linear cicatrix after healing. I apprehend that the seton is followed by considerably less disfigurement than the destruction of the part either by caustic or the ligature, which must necessarily be restored by granulation; for, instead of having one large cicatrix, as in the latter case, the greater portion of the integument covering the tumor being preserved in the former, little more than the scars produced by the needle remain, and hence the deformity is really trifling," &c.

The seton was applied to the following case, which was recommended to me by my friend Dr. Shaw, rather for the purpose of putting its efficacy further to the test than as superior to the other plans, any one of which might have been used, I apprehend, with an equally favourable result. To my intelligent pupil, Mr. A. W. Dumville, I am indebted for the narrative.

"William Baneroff, æt. 40, presented himself, May 19th, 1834, with nævus, situated on the right cheek, beneath the outer canthus of the eye; it was as large as a walnut, raised considerably from the surrounding surface, and of a venous colour; and, though chiefly involving the skin, it had extended to the cellular texture below, so as to represent the compound character of cutaneous and subcutaneous nævus. The patient states, that formerly it existed only as a mark, but that within the last three or four years it began to project, and has in-

* North of England Medical and Surgical Journal, vol. i. p. 66.

creased in all its dimensions. He cannot say, however, that it has undergone any change the last half year. A seton was this day passed through the tumor in a horizontal direction, which corresponded with its long diameter.

"May 24th.—The swelling indurated and tender, with some increase of bulk; but discharge not yet established.

"26th.—Discharge from the orifices free, and intumescence somewhat diminished, which induced Mr. F. to fear that the irritation was not enough to obliterate the diseased structure; he therefore partially withdrew the seton-thread, which he slightly touched with potassa fusa, and then returned it—a step which occasioned apparently very little pain.

"30th.—Suppuration pretty copious, and swelling reduced. The seton removed.

"June 4th.—The nævus greatly fallen, so that it appears scarcely elevated from the surrounding parts; it also has a firmer feel, as though its cells or vessels contain a solid deposition.

"10th.—Tumor little more than one-fourth its original size, and reduced to the level of the skin; but Mr. F. thinks it advisable to pursue the same plan with the remaining portion: hence, to-day, a small seton was passed in a perpendicular direction, and this was suffered to remain about eight days, after which it was withdrawn, having excited vigorous inflammatory action throughout the remaining growth.

"July 28th.—No appearance of the nævus is now discernible, and the surface of the integument covering the site of the tumor is smooth and equal, and scarcely shews a scar to entitle one to pronounce that a process of cure, such as the seton is intended to institute, had ever been employed."

In truth, the cicatrices at this time are so insignificant, that it requires a close inspection to discover them.

I am, sir,

Your obedient servant,

THOMAS FAWDINGTON.

Manchester, Oct. 25, 1834.

SURGICAL CASES

Treated in the Naval Hospital of St. Petersburg.

By HARRY LEEKE GIBBS, M.D.

Member of the Royal College of Surgeons of London.

Continuation of the Case of Iwan Nikitin, operated on for Subclavian Aneurism.

JAN. 26, 1823, 22d day.—Convalescence proceeding rapidly; beginning to use his fingers, which are of the natural warmth, and possessed of sensation. Friction employed night and morning with flannel and camphorated spirits to the whole of the arm, the breast, and parts about the left scapula.

29th day.—The increase of lax fungus so great, as to require the frequent application of the kali purum. By its use it is kept under the level of the integuments with the aid of straps of adhesive plaster; and by persevering in this plan, with moderate pressure, the wound was firmly consolidated on the 39th day (Feb. 12th), when he was walking about the ward, and enabled to assist in tying his neckcloth with the left hand. The patient had now recovered his former good looks, and the various functions of the body were regularly performed. A feeble tremulous pulsation was again perceptible in the brachial, ulnar, and radial arteries; the limb was becoming fleshy, and was well nourished by the numerous vessels of the shoulder and upper part of the arm anastomosing with those of the neck, breast, back, and scapula, and, to some extent probably, by the extreme branches of the left epigastric artery, which inosculate largely with those of the mammaria externa. In this way I imagine the blood to have been directly determined to the primary arteries of the arm for a short time after the operation, sufficiently so to stimulate them to a partial and imperfect action, and to maintain the vitality of the limb. But when the communication by anastomosis was fully established, and the secondary set of vessels were sufficiently dilated, the blood flowed, by preference as it were, into these new channels, and less was transmitted through the original vessels.

Feb. 27th.—Owing to the greater demand, the circulation had become more

equally balanced throughout the limb, and the pulsation in the large arteries was now readily felt synchronous with those in the right arm. Dismissed cured, and strictly enjoined to continue to wear his warm glove and flannel waistcoat; and to guard against the effects of cold, an order was obtained to give him the lightest work, and that too within doors. From time to time I had the satisfaction to watch the progress and restoration of the limb, and, at the expiration of a twelvemonth, to hear that he was enabled to pursue his ordinary occupation.

In the autumn of 1826 the subject of this interesting case was admitted into the medical department of the Naval Hospital, with febris catarrhalis, and oppression at the chest. By his express wish I visited him, and recommended a venesection of xxx. , which was purposely abstracted from the median cephalic of the left arm, the veins of which were turgid, and arterial action going on as vigorously as in the other arm. He soon left the hospital, and continued his work as cooper till the 9th December, 1823, when he was discharged the service (having served his time), and allowed the usual pension.

St. Petersburg, Sept. 25, 1834.

TREATMENT OF A CASE OF DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

THE case of delirium tremens succeeding apoplexy, related in your journal of last week, by Mr. Robbs, brought to my mind a similar one which occurred in my practice about the middle of last July. As the case ended favourably, you may, perhaps, consider it not altogether uninteresting.

I was called to a labouring man on Wednesday, who was lying in a state of insensibility. I was told he was in the habit of drinking freely, when he could obtain liquor. On the Sunday and Monday previous, he had been drinking. On calling to him, or shaking him, he would open his eyes with a wild stare, but seemed to have scarcely, if any, consciousness of what was go-

ing on around him. He would then relapse into his former state. His pulse was not much disturbed; on touching it, it gave the idea of being passively distended; the pupils were contracted; the face rather pale. I took about 12 oz. of blood from his arm: the pulse became softer, but in other respects he remained nearly as before. I then ordered him four pills, each containing one drop of croton oil; one to be taken every two hours. He took all these without effect. I then sent him four more, with similar directions. On the following morning (Thursday) I found him considerably better: the croton oil had acted well. He was sensible, but still had a wild look. His tongue was cleaning at the edges; there was a brown yellow fur in the centre. I ordered him to take immediately a pill of calomel and colocynth, and a purgative draught every three hours. At night, symptoms of delirium tremens came on, but he was not violent; he wanted to leave the house, but was easily restrained. I gave him tinct. opii, mxxl. immediately. On Friday morning he was not better. I then ordered the same quantity of laudanum every five hours. He took three doses without effect. I then directed them to give him a pint of porter, which was the drink he was accustomed to: he drank it, and fell asleep very shortly after. When I saw him again he was convalescent.

I should mention that in this case, as in Mr. Robbs's, there was rather profuse perspiration.—I am, sir,

Your obedient servant,

GEORGE PARSONS.

ON THE COMPARATIVE MERITS OF

DR. BELLINGER'S AND SIR C.
BELL'S WRITINGS

AND OPINIONS ON THE FUNCTIONS OF THE
FIFTH AND SEVENTH PAIRS OF
CEREBRAL NERVES.

By G. NEGRI, M.D.

Concluding Remarks.

THE description given in my last paper, of the origin of the facial nerve,

and its two distinct trunks, taken from the anatomical part of Bellingeri's Dissertation, so well supported by unobjectionable authorities, is quite sufficient to point out at once the fallacy of Mr. Alexander Shaw's remarks on the double functions attributed to it by that author.

I think it, therefore, unnecessary to bring forward, in this journal, that part which contains its physiology, as the reader may find, in the last number of Dr. J. Johnson's Medico-Chirurgical Review, a translation of Chapter II. of Bellingeri's Dissertation, which contains it.

From what, then, has been published, both in that quarterly, as well as in this weekly periodical, on the physiology of the fifth and seventh pairs of cerebral nerves, enough, I believe, of Bellingeri's work has been laid before the public, to exhibit a full and accurate idea of the Italian physiologist's doctrine on the functions of those nerves. Let him now be judged impartially, but only after his own words and opinions, and not through the highly improper and erroneous statements of incompetent critics.

Before, however, leaving this question, I must direct the attention of the medical profession to some other important points, so forcibly insisted upon by Mr. Alexander Shaw, in his already well-known article. "The fundamental principle," he says, "which pervades every sentence of Sir Charles Bell's works, is this (and it was announced in the unpublished tract.....printed in 1811)—that a single nerve cannot bestow both motion and sensation.....; whenever they are combined, it is a sign that the nerve is compound—that it originates by two distinct roots from the brain, or spinal marrow."—"It is not to be supposed that this principle.....rested altogether upon the experiments on the nerves of the face. It was not with these nerves that Sir Charles Bell began his investigations. It is well known that he commenced by experiments on the spinal nerves. It was after having ascertained by experiments (first made so far back as 1811, and repeated in March 1821), that the two roots of these spinal nerves possess distinct endowments, that he was led to examine the functions of the fifth pair, and to classify it with the spinal nerves."—"When we speak, therefore, of the validity of the proofs by which he established that

the fifth is a double nerve—the nerve of sensation and mastication—we must not omit to take into consideration the experiments on the spinal nerves, which corroborated his conclusions."

Now Sir Charles Bell, in his unpublished tract, printed in 1811, says:—"The spinal nerves being double, and having their roots in the spinal marrow, of which a portion comes from the *cerebrum*, and a portion from the *cerebellum*, they convey the attributes of both grand divisions of the brain to every part.....But the nerves which come directly from the brain, come from parts of the brain which vary in operation; and in order to bestow different qualities on the parts to which the nerves are distributed, two or more nerves must be united in their course, or at their final destination. Hence it is that the first nerve must have branches from the fifth united with it: hence the *portio dura* of the seventh pervades every where the bones of the cranium, to unite with the extended branches of the fifth: hence the union of the third and fifth in the orbit: hence the ninth and fifth are both sent to the tongue: hence it is, in short, that no part is sufficiently supplied by one single nerve, unless that nerve be a nerve of the spinal marrow, and have a double root—a connexion (however remotely) with both the *cerebrum* and *cerebellum*.*"

Thence it is evident, that although Sir Charles Bell had assigned particular functions to each of the double nerves of the spinal marrow, and performed experiments to ascertain this position, yet, in 1811, he considered still the fifth, together with the other cerebral nerves, as a simple nerve, entirely distinct from those of the spine: and when the English physiologist repeated those experiments, in March 1821, and was led to examine the functions of the fifth pair, and to classify it with the spinal nerves, the Italian physiologist had already published, in 1818, his classical Dissertation, which he publicly defended in the 9th day of May of the same year, before the Royal College of Medicine in Turin.

Now let us consider with what degree of anatomical evidence the fifth pair of cerebral nerves was, by Sir Charles Bell, classified with the symmetrical nerves of the spine.

In the sixth edition of his "Anatomy

and Physiology of the Human Body," printed in 1826, he expresses himself, on that point, in the following terms:—"Pursuing the subject, and still directed by the anatomy, the next matter of inquiry was to ascertain how far the fifth nerve of the encephalon corresponded with the spinal nerves. It was discovered that the fifth nerve bestowed sensibility on the cavities and surfaces of the head and face. . . . In short, in regard to their property of bestowing sensibility, the fifth and spinal nerves were identified.

"But was the fifth nerve, in *other essential circumstances*, similar to the spinal nerves? On recurring to anatomy, and comparing the fifth nerve of the encephalon with a spinal nerve, the resemblance, both in man and brutes, was very remarkable. In both nerves we see the double roots: the anterior root passing the ganglion, and the posterior root falling into it, or forming it. On following back the anterior root, we may perceive that it comes out betwixt the *funes* of the *pons varolii*, and, in fact, from the *crus* of the *cerebrum*.

"Observing that there was a portion of the fifth nerve which did not enter the ganglion of that nerve, and being assured of this fact by the concurring testimony of anatomists, I conceived that the fifth nerve was, in fact, the uppermost nerve of the spine—that is to say, the uppermost, or most anterior, of those nerves which order the motion, and bestow sensibility, in its extended sense, on the frame of the body.

"One circumstance I may notice in passing: the origin of the fifth nerve being above, or anterior to, the termination of the column of the spinal marrow for respiration, *it can receive no roots from it*."—Pages 386, 387.

Then, according to these *essential circumstances of similarity*—"The arrangement (says he) of this symmetrical system of nerves is this: there is an obvious division of the *medulla spinalis*, corresponding to the *cerebrum* and *cerebellum*; every regular nerve has two roots—one from the anterior of these columns, the other from the posterior: such are the fifth pair," &c.—P. 390. Therefore we must expect to find out the origin of the larger portion of the fifth entirely from the *cerebellum*, and that of the smaller one solely from the *cerebrum*: from it (in fact) all the nerves which are agents of the will pass

out." So Sir Charles Bell said, in his unpublished tract, 1811, at p. 27.

Now let us see how the origin of those two portions of the fifth has been made out in the anatomical part of Bellingeri's Dissertation.

"Of the Fifth Pair, or Trifacial Nerve*.

"This nerve emerges from the outer side of the middle annular prominence, and from the inner surface of the extremities of the peduncles of the cerebellum, where the latter are extended over the protuberance just mentioned.

"The actual origin of the nerve, however, is not there. As Santorini says:—"I do not call that the origin of the nerve, by which it emerges in a collected form from the annular protuberance, or the *pons varolii*; but that from which its very numerous and diversified fibres spring.' A great many anatomists have taken pains to assign the origin of the fifth; but they are by no means agreed on the subject. Santorini points out a threefold origin—namely, from the *crura cerebelli*, from the annular protuberance, and from a spot between the *corpora olivaria* and *pyramidalia*. Winslow coincides with Santorini as to the origin between the olivary and restiform bodies. Malacarne, on the other hand, denies this position, and admits but one origin only, from the peduncles of the cerebellum. But Gall has described and beautifully depicted the bundles of fibres which emerge between the *corpora olivaria* and *restiformia*; and he has, moreover, by deriving his illustrations from comparative anatomy, cleared up the doubt which Santorini entertained, as to the probable origin of those fibres from the olivary bodies themselves. Gall, in fact, found that in fishes, the ganglion from which the nerve proceeds was quite separate, and that the nervous filaments, even at their proper origin, are quite distinct from the common mass.

"It is therefore settled, that there is in the first instance a double origin of the fifth nerve—from the peduncles of the cerebellum, and the olivary bodies. Santorini, in his later researches, ascertained that there are no fibres arising

* For the translation of the following quotations, as well as for those in my preceding article, I am indebted to the kindness of the Editor, who thought it better, for the convenience of the readers, to have the Latin parts translated into English.

from the proper substance of the annular prominence; and Girardi, with praiseworthy diligence, has confirmed this view. Soemmerring adds, that he had seen the fifth arising from the medullary processes of the cerebrum, in the very floor almost of the fourth ventricle. But I doubt whether there be not some typographical error in that passage where he speaks of the ultimate extremity of the fifth pair being in the very wall of the *fifth* ventricle.

"The manifold fibres of the fifth, proceeding from different quarters, are all collected and formed into a single trunk, divided, however, from its very outset, into two bundles; so that the trunk of the fifth pair manifestly is composed of two portions. Scarpa has a fine drawing of the nerve as it proceeds from the substance of the brain, and in its twofold condition. Willis, too, and Vieussens, were acquainted with the same peculiarity; so that Paletta was quite justified in laying down two distinct nerves as proceeding from the lesser portion: in accordance with which I shall, in what follows, treat of both portions separately. One of these is anterior and superior in its origin—that is, the lesser portion; the other is posterior and inferior—the greater: both are composed of many and distinct fasciculi, separated at their very origin either by cellular tissue, blood-vessels, or medullary laminae; the larger portion is that which properly corresponds with the trunk of the fifth."

"Of the Greater Portion of the Fifth Nerve."

"The greater portion, at its egress from the peduncles of the cerebellum, presents a tubercle or medullary papilla*, much softer than the consistence of the fifth nerve: this was first detected and most minutely described by Bichat. Nervous filaments adhere to this papilla on every side: they have been reckoned at so many as thirty-four, forty-five, and even fifty, by Wrisberg. They are of unequal thickness at their origin, and as they proceed to the semilunar plexus; nor do they lie parallel to each other,

but are variously intertwined and connected as they cross. Willis, Vieussens, Haller, and Zinn, overlooked this peculiarity in their plates; but Prochaska has given a representation of it. This interlacing of the fibres is not only observable in the trunk of the greater portion of the fifth, but in the twigs proceeding from it, as Prochaska has described, and Bichat has properly noticed.

"Those fasciculi are gathered into a single trunk, which, wrapped in a sheath of pia mater, is carried along with the lesser portion of the fifth (lying then beneath it), to the sides of the posterior clinoid process, and is received in a furrow formed by the dura mater—a furrow peculiarly appropriated to this nerve, and distinct from the cavernous sinus, as Meckel has shewn, in contradiction to Vieussens and Winslow. There it forms the semilunar plexus, and acquires six times its bulk. The plexus just named is enveloped in condensed cellular tissue, called the *armilla* by Malacarne, and described by Haller as being richly provided with vessels. Hirsch has improperly called it the Gasserian ganglion, in compliment to his master. It is not a true ganglion, as is evident from the descriptions of Moscati and Malacarne: the filaments, though very closely intermixed, are by no means confused or incapable of being traced out—a task which has indeed been performed by the authors just quoted, as well as by Paletta and Wrisberg. So that, in its internal structure, it is of the nature of a plexus,—however, in its external, it may resemble a ganglion."

"Of the Lesser Portion of the Fifth."

"For the first exact description of the lesser portion of the fifth pair, we are indebted to the Italian, Santorini, who followed out its origin, structure, and course, with so much diligence and success, as to leave little to be added. Girardi, too, by his researches, illustrated this portion; and Wrisberg also contributed somewhat by his attentive investigations. The later authorities, Prochaska, Soemmerring, Scarpa, and Bichat, are now unanimously agreed that the fifth pair consists of two distinct portions.

"Bichat further believed that the lesser portion formed a nerve distinct from the trifacial. But Paletta taught that the

* Are these tubercles, or medullary papillae, to be considered as the gustatory ganglia from which the nerves of taste take their origin? This was the idea excited on my first reading this passage. Mr. Alexander Walker, in quoting the same description from Bellingeri, expressed a similar hypothesis, in his elaborate work on the Nervous System, lately published.

fifth pair was threefold—namely, the common trunk of the pair, or the greater portion; the crotaphitic nerve, or that which other anatomists mean by the lesser portion; and the buccinatory nerve: both which latter nerves I include and describe under the one name of the lesser portion, because, though distinct, they hardly in any respect differ in origin, course, structure, or functions.

“The lesser portion arises by a double cord from the inmost part of the crura cerebelli: one of these cords, the larger, the upper, and the inner, has its origin in the peduncles of the cerebellum, where they insert themselves into the annular prominence, and draw near the crura of the cerebrum. It consists of five or six filaments, gathered into a single trunk; it emerges from the crura cerebelli, anterior and superior to the common trunk of the fifth; it is then carried a little beneath the latter, and goes forward on its inner side. It has no connexion with the greater portion in this passage; and it issues from the skull through the foramen ovatum, along with another bundle of the lesser portion, and with the inferior maxillary branch, in front and on the inner side of both which it has its place. The bundle just mentioned corresponds with the crotaphitic nerve of Paletta; and upon leaving the skull it is divided into three branches, presently to be described.

“But the other fasciculus or root, and that the smaller and outer of the two, arises from the inmost parts of the peduncle of the cerebellum, and towards the lobes of the cerebellum itself. It emerges from the peduncles through a common opening along with the trunk of the greater portion. The root or bundle, according to Paletta, most generally consists of eight filaments, collected into one fasciculus, which is carried forward along with the common trunk of the fifth, on its outer side and towards the middle: it leaves the skull by the foramen ovatum, situated midway (but rather towards the inner side), between the crotaphitic nerve and the inferior maxillary. It corresponds to the buccinatory nerve of Paletta.

“The difference between the lesser and greater portions of the fifth pair consists in this—that they have distinct origins, and wholly separate tracks; but above all, the lesser portion neither

enters the semilunar plexus, called the Gasserian ganglion, nor is it enveloped in any manner by the armilla of Malacarne. Of this both Santorini and Girardi were well aware. It sends twigs, however, sometimes, to the plexus, as Soëmmerring notices after Girardi. There is a difference also in structure; for the filaments of which the lesser portion of the fifth is composed, are whiter, thicker, and stronger, than those of the greater portion. But the chief difference is that which Bichat points out—that the lesser portion presents the ordinary aspect of other nerves*.”

After this very minute and apparently accurate description of the real origins of the fifth, and more particularly of its smaller portion, supported by many classical authorities,—nay, so much in accordance with Mr. Mayo's beautiful drawing of the origin of the cerebral nerves, published in his *Outlines of Human Physiology*,—it may appear not unreasonable to entertain some doubt about Sir Charles Bell's deductions, both of the similarity of the fifth to the spinal nerve, as well as the functions of the *cerebrum* and *cerebellum*, and their anterior and posterior continuations down the columns of the spinal marrow.

Mr. Alexander Shaw, taking, however, no notice of these trifles, and always ready to censure Bellingeri for the supposed faults of his anonymous reviewer, goes on stating, “The confident tone of the reviewer.....would lead us to expect the most complete coincidence in the statements of the two physiologists—that they pursued the same method in conducting their inquiries, viz., first by examining the anatomy, and then by performing experiments; and that the results of their combined observations and experiments were the same.”

“The reader will find, on the contrary, in Bellingeri, (?) a direct opposition to the principle which I have stated—a totally different mode of pursuing the investigation—a signal clashing of opinions and statements with those of Sir Charles Bell; and he will

* The reader may now compare the description by Sir Charles Bell, given at p. 473 of his already-mentioned work on *Anatomy*, and examine the two wood-engravings, which “exhibit (as there is stated) the exact origin of the fifth pair.”

inquire in vain for any single point of harmony or concurrence on which to make out a case of anticipation."

Now I may, with more confidence, cry out with him, "The public—the intelligent public—especially the medical public, will not fail to look upon these exhibitions in their true light*."

Whatever may be the result, or the opinions entertained by the learned medical profession in this country about the importance and correctness of Bellingeri's physiological doctrines on this as well as on any other subject connected with the nervous system, that is a matter which is entirely unconnected with the present question, and which I have nothing to do with. I did not write, indeed, in support of any principle laid down by my learned countryman, but only to defend him against the misrepresentations of others: this I considered a sacred duty due to truth, to my country, and to the honour of Italian physiology.

The principal objects I had in view, therefore, were to prove—

1st. That Mr. A. Shaw had not, when writing his article, read Bellingeri's Dissertation; or, if he had read it, had not understood its contents properly; and thus has declared himself incompetent to give an opinion on such a physiological question. *He* is then to be considered "the *unlucky* foreigner, on any of whose 'assertions' we (and I fear all other persons) "must decline placing confidence."

2nd. Whatever may be Sir Charles Bell's claims, either on this or any other subject connected with the physiology of the nervous system, the 'Italian physiologist' had published, in 1818, a far more elaborate and accurate account both of the anatomy and physiology of the fifth and seventh pairs of nerves, than any published by the 'English physiologist,' from his first paper, read before the Royal Society, in July 1821, to the last one, read in May 1829: or, if Mr. A. Shaw like better, from the *unpublished tract* printed in 1811, where the fifth is yet considered as a single nerve, to the last work on the nervous system, published in 1830, which "must be supposed to present Sir Charles Bell's matured opinions on that subject."

3rd. When Bellingeri was writing his

opinions in 1818, or even before, on the physiology of the fifth and seventh pairs of nerves, and by performing *experiments* in living animals, drew the first correct conclusion on the function of the seventh, he could not have derived any information from what had not yet formed a subject of examination in Sir Charles Bell's mind. Bellingeri had a nearer source of instruction and excitement for such inquiries, in the professor of anatomy to the University of Turin, the celebrated Rolando, one of the most distinguished modern inquirers into the structure of the brain, whose death, together with that of Scarpa and Paletta, Italy had lately to deplore.

4th. Although Bellingeri went through the natural intricacy of the nerves of the face from their origin to their last terminations, he deduced their functions both from anatomy and physiology, as well as from pathology, and experiments on animals, without increasing their "*pristine confusion*" by the introduction of hypothetical superadded system of nerves. Their source of action was always referred to distinct points of origin from the encephalon, and their various functions explained either by the influence of a simple or of a compound nerve.

At last, the Italian physiologist has published his opinions on the functions of the fifth and seventh pairs of cerebral nerves, as mere deductions—nay, as *more probable conjectures*, derived by his extensive researches into the history, as well as patient inquiries into the anatomy and physiology, of those two nerves, and did not proclaim them to the world as his own discoveries.

I shall, then, conclude with the following quotation, so very aptly introduced by Mr. Swan, in his article on the merits of Willis and many others, regarding the functions of nerves.

"Oro miserere laborum
Tantorum, miserere animæ non digna ferentis."

After all, it remains only for me to return my sincere thanks to the Editor, for the liberal and unrestricted manner in which my articles were allowed to be published in the pages of this respectable journal.

CICERO.

PROVIDENTIAL PRESERVATION
OF THE MEDICAL EVIDENCE,
AND BLASTING OF THE DIABOLICAL HOPES
OF THE CORRUPTIONISTS.

"He made the giants first—and then he slew
them."—TOM THUMB.

NEVER was the description of the prodigies performed by the renowned personage alluded to in the above quotation, more entirely appropriate, since it was first indited, than it is to the feats of havoc and destruction enacted, in his last crusade against the "corruptionists," by our incorruptible contemporary. The fire kindled up at once certain old associations; and straightway he blazes forth in a fine strain of generous indignation. The anticipated rejoicings of imaginary persons over the supposed destruction of the evidence recently taken before Mr. Warburton's committee are given with all the fidelity which is characteristic of works of fancy, and with a minuteness that extends to the very expressions which they did *not* use! Ah! little knew they with whom they had to deal;—one who could publish their opinions before they were formed, and quote their words before they uttered them!

But we must be more explicit. Our renowned contemporary—he who makes the giants whom he slays—the great TOM THUMB of medical reform, indulges his readers with a description of the rejoicings of the "medical jobbers, schemers, and corruptionists," on the occasion of the houses of Parliament being burnt; they, the said "jobbers, schemers, and corruptionists," being first assumed to have imagined that the

evidence taken before the medical committee had been reduced to ashes. This affords the writer an opportunity to burst forth in a lofty tone of patriotic indignation, mingled however with natural exultation, at the discomfiture of his opponents, who, we are told, are "exposed, defeated, and disgraced," to say nothing of their being "scouted, derided, and despised." The manner in which this great victory of liberalism over tyranny was obtained, and in which the papers were rescued from destruction, is told in language glowing in proportion to the fiery perils it depicts, wherein Othello's "hairbreadth 'scapes in the imminent deadly breach," and all his "moving accidents by flood and fire," are left at an immeasurable distance.

Nor would we willingly pass unnoticed the interesting but distressing fact, that some of the papers "were found next morning in the street, damming up the gutters*"!! Think of Mr. Wakley's anathemas against the "ignorant, conceited, malignant, lying, boasting, hospital surgeons," (we love to give the exact words), reduced to so degraded a situation!—To be sure, what dirty evidence it must then have been! To have been consumed in the blaze of the conflagration would have had something characteristic in it; but

"To lie in cold obstruction and to rot!"

and after d——ing the "corruptionists" to corrupt in "damming the gutters!!" No wonder that the bare idea should have roused him to that burst of mingled suffering and triumph which it is our fortune to record.

Much is said of the value of the documents thus preserved, and certainly they ought to be worth something, if we may judge by the many thousands of pounds which they have cost, or the

* Vide Mr. Dermott's letter in the newspapers and *Lancet*.

time which has been occupied in collecting them; and in serious and sober sadness we declare, that few things would have been more vexatious than their destruction. There was, however, one small difficulty in the way of the fire effecting this calamity, which our contemporary, in the heat of his argument, has overlooked—viz. that it was impossible. The greater part of the evidence, if not the whole, has been for some time in the hands of the members of the committee; nay, it had actually been printed for the use of the House; and, besides, even had neither of these events taken place, there still exists a resource in Mr. Gurney's original short-hand notes. We suppose, also, that the fire did not destroy Mr. Spottiswoode's types, and that the cost of paper and a little correction might easily have been provided, so as to damp the rejoicings of those delighters in fire, so glowingly described by our contemporary, and of whom Empedocles was but an imperfect representative.

Sir Henry Hallford, we are told, displayed great and particular exultation on the subject of the fire; but it happened that Sir Henry was at his country-seat at Wistow Hall; and we can only account for this blunder by the footman with whom our contemporary communicates having been absent with his master. (We assume one of the domestics to be his correspondent, because all the *communications* about the learned baronet bear internal evidence of proceeding from some disappointed lackey.) It thus appears that Sir Henry Hallford could have had little cause for "rejoicing," as, whatever time he heard of the fire, he must have been aware that it could not have burnt Mr. Spottiswoode's types, nor Mr. Gurney's notes, nor the copies of the members of the Committee, among whom was his own son, Mr. Hallford. We certainly differ from the learned president in several matters

touched upon in his evidence regarding the College of Physicians; but that he has the remotest wish that it should be concealed, or the slightest desire to prevent it from being doled out in sixpenny pamphlets to the readers of the *Lancet*, is a fantasy that exists only in the overheated brain of our contemporary—if, indeed, it be more than a mere trick to give a spur to curiosity, and push the flagging sale of what has proved a very bad speculation,—we mean Wakley's surreptitious edition of the *Parliamentary Medical Evidence*.

One thing, however, we gather from our contemporary's observations on the fire: it would seem to have illuminated him as to the fact, that the idea of a Royal Commission is not yet lost sight of; but the nature of his reference to the subject is such as to shew either that his information is yet worse than usual, or his habitual misrepresentation too strong to be laid aside even on the commonest occasions. He would have us believe that the lately revived idea of a Commission originated with the "corruptionists and monopolists;" whereas it came from one of the first, if not (on such points) the very first, among the ministers of the Crown; in consequence, too, of representations recently made at the seat of that University the graduates of which have been heretofore habitually designated in the *Lancet* by the sobriquet of Dubs; but which it now very consistently charges its opponents—and falsely charges them, with representing as "a mere grinding establishment." That a Royal Commission should become necessary would, we think, be greatly to be deplored, after all the time and trouble, and money, which have already been expended. An impression, however, was early imbibed by some leading members in both houses of Parliament, that too much party feeling was exhibited in the Committee room; and we are quite satisfied, from

what we regard as good sources of information, that should any attempt be made in conformity with the views of the "One Faculty" visionaries, it will be scouted even by the Commons; while its passing through the Peers has never been regarded as otherwise than chimerical. Meantime, from admitting every blockhead who volunteered his crude opinions to be examined, the inquiry has been protracted till all interest and curiosity about it are lost; so that, as our contemporary has ere now found to his cost, the public will not give even sixpence for the evidence. Indeed, it is quite notorious that the *public* never did care one farthing about the matter—nay, they do not even know what "medical reform" means, as any one may be convinced who will take the trouble to put the question to his next neighbour. But, on the other hand, the expense to the country has been great beyond all anticipation; so great, indeed, that it has proved no inconsiderable source of embarrassment—the amount and the ostensible cause being so utterly disproportionate.

As to our contemporary, however, we must candidly admit, that though there be a great deal of impudent invention and absurdity about his account of it, still that a fire, and, above all, a fire by some supposed to have been the work of an incendiary, should have been interesting to him, was on various grounds to be expected, and we ought not to complain that he has made the most of it. Besides, be it known that he was himself examined just before the close of the inquiry, and it must have been a great shock to his feelings to learn that the spouting in the Committee room, which followed next after his own, should have thrown so much cold water on the cause of reform, sweeping away all he had said, and anticipating its appropriate fate, by converting it prematurely to the inglorious purpose of "damning up the gutters."

LONDON UNIVERSITY HOSPITAL.

THERE has been a kind of exhibition of this building during the last few days, in order, we presume, to convince the public that it is actually completed. We are much opposed, as our readers well know, to the system of humbug which has prevailed to such an extent about the *University*, and to the *ad captandam* displays in which its conductors so frequently indulge. But this shall never prevent us from doing the parties justice; and as we did not think it possible that the plastering and whitewashing of the new edifice could have been accomplished in so short a space, we think it due to them to announce that it has been executed with almost incredible celerity, and that it looks very smart and comfortable. The building, though small, is well contrived, and has an operating theatre behind, which, though not yet ready, will soon be so. Whenever the requisite number of beds is filled, the hospital will no doubt be "recognized;" and it is of importance for students that this be done soon, as their attendance will not begin to count but from that date.

By the way, we wish the parties would agree about the name. The secretary, in his official announcements, calls it the "North London;" the *Lancet* and Dr. Elliotson denominate it the "London University" Hospital. By which cognomen is it to be permanently designated? We think the latter decidedly the better of the two.

SURGICAL REPORTS

FROM THE

LONDON DISPENSARY.

By R. R. ROBINSON, Esq.

Surgeon to that Institution.

CASE I.—*Hydrocele on the left side Palliative Treatment.*

EDWARD MAY, *æt.* 30, admitted September 13th, was riding on horseback last January, and struck the left testis against the pommel of the saddle. No pain followed, but shortly afterwards the left side of the scrotum swelled. The swelling has since increased gradually; the left testis appears now nearly as large again as the other; surface is even; shape globular;

it is extremely hard; there is no sense of fluctuation; it is not transparent, but there is not the least pain produced upon pressure. Some degree of doubt occurred in this case: its being caused by a blow—its extreme hardness, and the total absence of yielding, or fluctuation—were in favour of enlargement of the testis. On the contrary, the total absence of pain from the first, the uniform surface, the globular shape, and the absence of fever, induced the belief that it was hydrocele, and not inflammation, or enlargement of the testis. It was accordingly punctured with care, and six ounces of clear serum evacuated. The testis was healthy, and it was recommended that the tunica vaginalis should be injected; but as he had urgent business, and was about to leave the country, that was not done.

CASE II.—Hydrocele on both sides—Palliative Treatment

Thomas Aldam, æt. 61, admitted July 21st; subject to dysuria occasionally; had the left tunica vaginalis tapped two years and a half ago, and a pint and a half of fluid evacuated. Both tunicæ vaginales tense, and free from pain; both tumors began at the lower part, and enlarged gradually; no hernia; pain in the back, from the weight of the tumors. They were both tapped to-day; from the right side, three-quarters of a pint, from the left a pint and a half, of straw-coloured, clear fluid, were withdrawn. The testis appears healthy, but the right rather harder than the left. The fluid collected again in each tunica vaginalis. He died some months afterwards, of malignant disease of the stomach.

CASE III.—Inguinal Hernia and Hydrocele—Palliative Treatment.

John McDonald, æt. 40, admitted May 22d; the subject of pulmonary disease many years, and inguinal hernia on the left side, which is easily reducible, and does not proceed below the left groin; the left tunica vaginalis much larger than the other, forming a globular smooth tumor, with a sense of fluctuation, evidently a hydrocele, as it has been tapped several times. A trochar was introduced, and 16 oz. of straw-coloured serum withdrawn.

CASE IV.—Inguinal Hernia on both sides—Hydrocele on the right—Palliative Treatment.

Isaac Carlier, æt. 70, admitted December 31st. First perceived a rupture in the right inguinal region 30 years ago; two years afterwards, a rupture occurred also in the left side; both have been kept up tolerable well by a double-headed truss. About nine or ten years ago, he perceived

a swelling at the lower part of the right testis, which gradually increased, but was entirely free from pain. About three weeks ago, he first felt a dragging sensation in the loins, which continues. Right tunica vaginalis is much distended and elastic, apparently from fluid within it. The hernia on this side descends, upon coughing, into the inguinal canal, but not otherwise; the opening is large, and the return easy. Over the upper part of the left tunica vaginalis, there is a large soft swelling, like omentum; which, upon pressure (which produces slight uneasiness), can be made to proceed towards the external abdominal ring, but does not altogether disappear. The testis cannot be distinctly felt on this side. He is very feeble, and has had dyspnoea and cough for some years. The right tunica vaginalis was punctured, and a pint of green, clear, albuminous fluid was withdrawn; when the dragging in the back was immediately relieved. As he was much out of health, the tunica vaginalis hardened, and the right testis a little enlarged, a radical cure was not attempted.

CASE V.—Large Hydrocele of five years' standing—Slight tenderness of the left Testis—Palliative Treatment—Fluid slowly re-accumulated.

Joseph Nelson, æt. 55, admitted April 17th. A healthy man; has had a swelling of the testis on the left side five years, which began at the lower part, and increased gradually, without any pain. There is now a very large smooth globular tumor on the left side of the scrotum, which obliterates the penis; is very heavy, and elastic. A trochar introduced gave exit to two pints of clear, high-coloured, albuminous serum. Tunica vaginalis not thickened; testis rather small, soft, and slightly tender when pressed, which, he says, has been the case many years.

May 19th.—Quite easy, except when the testis is pressed; no fluid detected in the tunica vaginalis.

August 28th.—Left tunica vaginalis rather larger; no pain, but there appears to be a slight return of fluid.

Sept. 29th.—Left tunica vaginalis decidedly more enlarged, and now clearly contains a fluid; which, however, appears to re-accumulate slowly.

CASE VI.—Hydrocele of long standing—Gonorrhœa—Inflammation of the Testis—Palliative and Antiphlogistic Treatment radical.

J. H., æt. 46, admitted September 8th, 1832, has had enlargement of the left side of the scrotum from youth, which never gave him any uneasiness, not even when as

a sailor he scaled the ladder on board a ship. Had spurious connexion when drunk, a month ago; about a week afterwards, he perceived a purulent discharge from the urethra, which has entirely ceased the last few days. He got wet through on the 4th and 5th instant, after which he experienced pain and increased swelling of the left testis; for which 24 leeches have been at three separate times applied, and mercury given, with considerable relief. Mouth not yet sore; many enlarged and varicose veins on the scrotum, which is rather flaccid. Left testis much longer than the other; enlarged, indurated, and weighty; painful when dependent, or pressed—easy when supported and untouched. There is also evidently a considerable quantity of fluid anterior to the testis; rigors when the swelling of the testis first increased, but none since; no fever; bowels costive.

Lot. Plumb. Cal. gr. iij. Opii, gr. $\frac{1}{2}$, n. et m. Mist. Cath. Ant. bis die. Hirudines rep.

September 14th.—Pain nearly gone; testis softer and smaller; slight return of gonorrhœa the last few days.

Rep. Lot. et Mist. Pil. Hydr. gr. iij. o. n.

October 3d.—Gonorrhœa increased the last week; testis of late more painful, notwithstanding leeches have been several times applied, and the mercury continued. I this day punctured the tunica vaginalis anteriorly, and gave exit to about a pint of serous fluid of brown colour, and coagulable by heat; *no flakes of lymph*; testis was felt posteriorly; was not much enlarged, but was very tender to the touch.

Rep. Hirud. Cal. gr. iij. Opii, gr. j. n. et m.

7th.—Mouth very sore; pain in the testis entirely gone; not tender to the touch; softer; discharge from the urethra nearly ceased; epididymis enlarged and hard.

17th.—Discharge from the urethra again copious; posterior part of the testis still hard; no fresh accumulation of fluid.

Mr. Scott's mureurial dressing applied to the scrotum.

22d.—Gets up daily; much easier; epididymis much smaller; thickening scarcely perceptible; copious discharge from the urethra.

Liq. Postass. Bals. Copaibæ, a. 5ss. ter die.

November 2d.—Discharge nearly gone; testis quite easy, except when it wants dressing, which is about every four days; not much harder or larger than the other; walks about well.

March 4th, 1833.—I saw him to-day; testis its natural size. Tunica vaginalis thickened, but devoid of fluid. Gonor-

rhœa continued on and off until a month ago; since which he has been entirely free from it.

CASE VII.—*Hydrocele on the right side, injected with wine and water—Radically cured.*

Henry Stone, æt. 68, admitted October 29th; the subject of hydrocele twelve months; was tapped six months ago. There was a rather small, smooth, globular tumor on the right side of the scrotum, entirely devoid of pain, which was punctured, and eight ounces of clear straw-coloured fluid, readily coagulable by heat, withdrawn. The tunica vaginalis seeming healthy, and the testis not enlarged, about the same quantity of wine and water, in the proportion of two-thirds of the former to one of the latter, was injected, and allowed to remain five minutes: it produced only trifling pain, which extended towards the groin; and on its removal the scrotum became much corrugated.

P. P. 3j. Lot. Plumb. Support.

October 31st.—Some pain in the groin; scrotum tender to the touch; no fever.

November 12th.—No pain; tumor as large and as tense as before the operation.

P. P. 3j. Ung. Hyd. fort.

26th.—Tumor continues free from pain: it is continually diminished in size, and less tense.

Rep. Ung.

I have seen him lately: the fluid was all absorbed, and did not return; the testis is the same, both in size and feel, as the other, and the cure is perfect.

CASE VIII.—*Hydrocele on the right side, injected with a solution of Sulphate of Zinc—Much Inflammation of the Testis—Cure radical.*

Richard Kingwell, æt. 63, admitted the 13th of December, with a hydrocele of the right tunica vaginalis; it had been forming for two years and a half, and had been tapped twelve months ago. Upon introducing the trochar, 3xij. of fluid were withdrawn, the testis and its coats appearing healthy; a solution of sulphate of zinc (3ss. to eight ounces of water), was injected, and retained for five minutes; some pain, especially about the back, supervened, and syncope. On the following day, the pain in the back had greatly increased; the testis was hard, exceedingly tender to the touch, and evidently inflamed. The veins of the scrotum were opened, and a good deal of blood removed; he was kept in bed, a cold lotion applied, and mercury taken to affect his mouth, under which the inflammation of the testis entirely subsided; no fresh collection of fluid ensued; and on the 7th January he was discharged cured. I have

seen him since, some time after the operation, and there was then no fresh accumulation.

CASE IX.—*Hydrocele treated radically by the injection of Lime-water.*

James Donald, æt. 70, the subject of asthma, admitted March 22d. Has had a hydrocele forming on the right side some years, which was punctured about thirteen months ago, but, as the trochar was being withdrawn, he flinched, and brought the canula out also; about ʒij. of clean serum escaped, and a little passed into the cellular substance of the scrotum. To-day the hydrocele was punctured again; ʒviij. of straw-coloured fluid were withdrawn, and the same quantity of lime-water injected, and retained for five minutes; it produced some smarting, faintness, and corrugation of the scrotum.

March 23d. — Tumor very painful throughout yesterday afternoon, entirely free from pain to-day, but nearly, if not quite, as large as before the operation.

April 22d. — Tumor certainly smaller, but still containing a good deal of fluid; entirely devoid of pain.

August 18th. — He called on me to-day; the fluid is entirely absorbed, and has been so for some time; the testis is quite healthy, and there is no vestige of disease.

CASE X.—*Hydrocele on the left side—Lime-water injection—Disease of the Testis on the right side.*

John Perry, æt. 25, admitted March 7th, a thin, feeble, sallow man (naturally), perceived a swelling on the left side of the scrotum twelve months ago, which commenced below, and never gave him pain till it was weighty; it was tapped ten months ago; a clear fluid was discharged, and it soon filled again. The scrotum is now the seat of two distinct swellings, one on each side of the raphe. On the left side the tumor is large, soft, devoid of feeling, fluctuating, and, by a candle, diaphanous; on the right, pyriform, smaller, hard, though smooth on the surface, and rather painful, especially on pressure over the cord; not diaphanous; and slight cough and dyspnoea. Lungs, upon auscultation, sonorous, and apparently healthy.

Linetus; Pil. Scillæ, g. ij.; Pil. Hydr. g. iij. n. et m. Vesic. sterno.

March 12th. — Cough much diminished; looks better; no fever. Left tunica vaginalis punctured; 10 oz. of straw coloured fluid removed; testis small, and healthy. Eight oz. of lime-water were injected, and allowed to remain six minutes; it produced no pain, but a slight degree of faintness.

13th. — Scrotum again a good deal distended with fluid; a sharp pain in the hips and loins a few hours after the operation, but that is gone off.

20th. — Left side of the scrotum much less again; no pain here, but a good deal of pain on the opposite side, especially about the cord; health somewhat improved.

Magn. Sulph. ʒss. ex Inf. Gent. C. ʒiss. ter die; Lot. Plumb.; and support.

April 4th. — Tumor on the right side still painful and large; left side still further diminished in size. Right side dressed in Mr. Scott's way.

Dec. Cinch. e. Tr. Iodinæ, ʒ. v. ter die.

The scrotum was twice dressed in the same way, at a week's interval; the pain went away, and the tumor on the right side was certainly diminished; but after this he never applied again. I think it is not improbable that the disease of the lungs, under which he certainly laboured, (for I suspected phthisis at the time), advanced and destroyed him.

REMARKS.—The preceding cases will, I trust, prove interesting to your junior readers, as they illustrate some of the obscurities and combinations of hydrocele, and the varieties which, in its treatment, it is necessary to adopt.

In the first case is seen some obscurity in the diagnosis; the tumor having been produced by a blow, its extreme hardness, and the total absence of yielding or fluctuation, at first induced me to think the disease enlargement of the testis, resulting from chronic inflammation; on the contrary, the total absence of pain from the commencement, the uniform and even surface of the tumor, its globular shape, and the absence of fever, were much in favour of hydrocele, under which impression the tumor was carefully punctured, and its nature at once ascertained.

In the second case, a hydrocele formed on both sides, and here there was little or no obscurity; for there was no appearance of hernia—the rings were closed—the tumors began to form slowly, commenced at the lower part, and never disappeared after they had first formed. The even surface of the tumors, the absence of pain, except in the back, which was evidently owing to their weight and dragging, —both being nearly of the same size, both very considerably larger than natural, and fluid, to a great amount, having been previously removed from the left side by tapping,—at once pointed out the nature of the case.

In the third case, the combination of hydrocele with hernia was seen; but the

two diseases were so separate and distinctly marked, that no mistake could be made. The hernia was small, did not descend beyond the groin, and was easily returned. The lower tumor had been previously tapped, and fluid removed from it.

In the fourth case is seen a hydrocele on the right side, and an hernia in both groins; but, as in the preceding case, there was no difficulty in forming a correct diagnosis.

The fifth case is interesting, from the very slow return of the fluid after its removal. Four months after the operation, no fluid was detectable; and it might then have been fairly reported as an example of the palliative plan being radical. It shows now, however, the necessity of being cautious, and taking time, that we may not form an erroneous opinion.

The sixth case shows the very common combination of gonorrhoea and inflammation of the testicle; the latter was apparently brought on, partly by the suppression of the purulent discharge, and partly by exposure for two successive days to cold and wet. This is peculiar as well as interesting, from there having existed for years a collection of fluid in the vaginal coat of the testis, which was inflamed, and from the palliative treatment proving radical. The inflammation being a different and more powerful action than the mere serous exhalation, appears to have stopped that, and to have led to the effusion of coagulable lymph, by which the vaginal coat was partially or completely glued to the testis. The thickening of the tunica vaginalis, and the effusion of coagulable lymph, is sometimes very considerable. I have in my possession a preparation, in which, from inflammation, the vaginal coat covering the testis is fully a quarter of an inch thick from intestinal deposition, and the whole membrane is lined with a thick and beautifully vascular false membrane: this inflammation and its effects were produced by the injection of undiluted port wine.

The four last cases give us an opportunity of comparing the effects of different injections. In Case 7, port wine and water were used, in the proportion of two-thirds of the former to one third of the latter. Eight ounces of this were injected, and allowed to remain five minutes; the patient's age was 68. It was productive of very little pain. Effusion again occurred in a few days, but it was all absorbed again in the course of a few months.

In the eighth case the man's age was 63. Eight ounces of a solution of sulphate of zinc (in the proportion of a drachm to a pint) were employed as the injection, and allowed, as in the preceding case, to remain five minutes. Some pain,

especially in the loins, and syncope, immediately followed, and severe inflammation of the testis subsequently ensued, requiring rest, scarification of the scrotal veins, and mercury for its removal. There was, however, no return of effusion.

In Cases 9 and 10 I employed lime-water, in consequence of my friend, Mr. Curling, having mentioned that it had been successfully used in these cases. In one the man's age was 70; the quantity injected half a pint; the time it was allowed to remain five minutes. It produced some smarting, faintness, and corrugation of the scrotum. On the following day the effusion was nearly, if not quite, as extensive as before the operation, but there was no pain or other inconvenience; in a month it had decidedly decreased, and in less than five all vestige of fluid had disappeared.

In the other case the patient's age was 25. The same quantity of fluid was used, and it was allowed to remain six minutes. On the following day the accumulation was nearly as great as before the puncture, but there was no uneasiness, though a sharp pain in the loins and hips was experienced a few hours after the operation.

As this man was much out of health, I was perhaps scarcely justified in resorting to the radical cure; but the patient had been much annoyed by the weight of the tumor, had had the fluid removed once before, was very anxious to get rid of his complaint altogether, and had materially improved in his general appearance under the means employed. I therefore ventured to try the lime water, as it did not seem likely to produce excessive irritation. That I might prevent this as much as possible, I kept him in bed, and fortunately no ill effects followed. I think from the rapid re-appearance of the fluid, and its subsequent diminution, that the whole would in time have disappeared. I regret, however, that I have nothing but conjecture to offer upon this point.

In the last case there also existed disease (I believe scrofulous inflammation) of the testis on the side opposite to the hydrocele, and afforded a good opportunity of contrasting the symptoms of each. On the hydrocele side the swelling had gradually formed, had commenced below; was large, soft, fluctuating, diaphanous, and devoid of pain. On the side where the testicle was diseased, the tumor was smaller, more rapid in its formation, hard, inelastic, not diaphanous, and very painful, especially on pressure.

In these ten cases, it will be observed that the hydrocele occurred in *four* instances on the *right*, in *five* on the *left*, and in one instance on both sides.

ST. GEORGE'S HOSPITAL.

CASES REPORTED BY A PUPIL.

CASE I.—*Rheumatism of the Heart, with Paralysis.*

ANN REDMAN, æt. 37, admitted Sept. 17th. Has been ill for the last four months from repeated attacks of acute rheumatism. The complaint shifts from one part to another. On admission, the hands and fore-arms were red, swollen, and very painful; but warmth appeared to afford her relief. There was pain in the chest, laboured inspiration, and an irregular and considerably increased action of the heart and great vessels, which was communicated to the jugular veins. Pulse 100; tongue white. She was ordered to be immediately bled, and to take

Cal. gr. iij.; Opii, gr. j. M. sum. t. d. formâ pil.; Hanst. Sennæ, quotidie mane.—Fever diet.

Sept. 20th.—Rheumatism of limbs much better; pain in chest much relieved; can breathe and lie down without difficulty; pulse 120, irregular and intermitting.

25th.—Rheumatism and pain in chest entirely gone; mouth affected by the mercury; countenance very pale; pulse still weak and intermitting.

Omit. Med.; utatur. Gargar. aluminis.

26th.—Was attacked yesterday afternoon with sudden difficulty of breathing, which was very shortly followed by complete paralysis of the right side. Suffers pain in the region of the heart; inspires with great difficulty; lies motionless, with a cold sweat bedewing her skin, and is scarcely capable of replying to the questions put to her. Was bled immediately after the paralytic fit; blood not buffed nor cupped.

R Sp. Æth. Sulph. ʒss.; Ammon. Subcarb. gr. iij.; Mist. Camph. ʒiiss. M. sum. 4tis horis.

28th.—Died at one o'clock P.M.

Secitio cadaveris.—The pericardium was so firmly adherent to the heart, that it could not be detached from it. The heart was of the ordinary size; but when cut into, its substance was found much softer than natural: its valves were healthy.

The brain was carefully examined; but, with the exception of a more than usual emptiness of the meningeal veins, no remarkable appearance whatever was discovered.

REMARKS.—This case, at the commencement, presented nothing remark-

able. There was simply acute rheumatism of the upper extremities flying about from part to part; and at length, as frequently happens, more especially in this kind of shifting rheumatism, the disorder was transferred to the heart. The usual remedies—bleeding, with frequent doses of calomel and opium, and opening medicine, sufficed to relieve the patient. With the exception of an intermitting pulse, every thing was going on well, when suddenly she was struck with paralysis.

It became immediately a matter of speculation among my fellow pupils to account for this fatal superaddition to the patient's complaint. It was attributed by some to an increased impetus given to the blood by the efforts of the heart to make up by force what it wanted in freedom of action; which the vessels of the brain being unprepared for, or not in a condition to withstand, rupture and apoplexy followed. Others were disposed to assume that some degree or kind of inflammatory action had arisen in the substance of the heart itself, weakening its power of transmitting to the various organs their required supply of blood, and thus interrupting, as one effect, the circulation of the brain.

The post-mortem appearances would seem to favour the latter explanation. The heart was found softened, and the brain appeared drained of its blood. A physician of eminence, Dr. Farre, regards this softened condition of the heart, by which its muscular power is enfeebled, as the effect of inflammation of its substance; and that palsy may depend upon an insufficient supply of blood being sent to the brain, will, I suppose, scarcely be doubted. Why the paralysis should have been confined to one side, affords matter for further speculation.

CASE II.—*Intermittent Lumbago cured by Quina.*

John Harding, æt. 49, admitted August 20th.—Has been in the habit, from the nature of his occupations, of being subjected to sudden changes of temperature. About six months ago, first felt some stiffness across the small of the back; at the end of three weeks this amounted to severe pain, forbidding motion, and confining him to the recumbent posture. His suffering was always more severe at night. This state of things had continued up to the period of his admission, on which occasion a careful examination was made of the parts affected, but no preternatural appearance whatever could be detected about the seat of pain. Tongue clean; pulse 100, weak; skin not hot; urine clear—does not coagulate by heat or acids.

20th.—Greatly relieved.

27th.—Quite free from pain; sleeps well; and is much improved in health.

REMARKS.—Those who are in the habit of attending the practice of hospitals, will have experienced the difficulty frequently met with, of getting from patients, on their admission, an intelligible account of the ailments for which they make application for relief. The above was a case in point. It was not made out till Harding had been some time in the hospital, that the pain observed stated periods of attack and subsidence—partook, in short, of an intermittent character. As soon as this was observed, the specific power of quinine in intermittent disorders was called in aid, and soon produced a complete removal of the affection.

The colchicum and guaiacum were given under the impression that the pain was of a rheumatic nature; but the perfect inefficiency of those medicines to produce alteration of any kind in the patient's condition, soon induced the physician to have recourse to others. The veratria alone, before the quina was prescribed, seemed capable of exercising any influence over the malady; but when the true character of the affection became obvious, the sulphate of quinine was employed, and with the success above recorded.

GUY'S HOSPITAL.

Operation of Tying the Femoral Artery.

THE operation of tying the femoral artery, for the cure of popliteal aneurism, was performed at this hospital, by Mr. Bransby Cooper, on Tuesday morning last. The patient was a middle-aged man, and was admitted into the hospital but a few days back: the disease had existed about three months. The case, before the operation, had every favourable appearance, but some little difficulty had to be encountered during the performance of it. The limb was rather œdematous, from the pressure produced by the disease. The operation was commenced in the usual manner. On dissecting down to the sheath, an arterial branch of some considerable size was divided, and bled sufficiently to require a ligature: this Mr. Cooper believed to be a large muscular branch, passing to supply the sartorius. The sheath was readily exposed, which, when opened, brought into view the artery; but owing to the size of it being much less than usual, the operator hesitated before he passed the ligature around it, and requested Mr. Callaway, who was near, to convince himself that it was the right trunk. It was then secured, and the wound drawn together with adhesive plaister. When this patient had been removed, his place was quickly filled by an elderly man, who had to submit to amputation of the leg, for disease of the foot. This operation was performed by Mr. Morgan, with his usual neatness and quickness, for which he stands so particularly pre-eminent. The circular opening was practised, but some little trouble and time were required before the vessels could be secured.

The theatre was unusually crowded; many pupils were obliged to leave without being enabled to obtain a glimpse of the operations: indeed, the inconvenience arising from the smallness of the place was at this time particularly evident. How the governors of an institution so charitable and wealthy, can suffer the present small theatre to remain, is, indeed, a mystery.

A PUPIL.

ON CERTAIN MENTAL ILLUSIONS.

In a memoir read by M. Esquirol before the Institute, in October, 1832, the learned author endeavoured to establish the distinction between mental hallucinations and mental illusions: the former are the mere offspring of the disturbed mind, arising without any evident cause, and re-

ferable to no distinct operation preceding them; whereas the latter are the results of certain impressions made upon the body, but the nature of which impressions the insane strangely mistakes and perverts: the former are altogether mental phenomena; the latter are mental indeed, but generated from and depending upon previous corporeal influences. These corporeal influences are very generally painful sensations, either on the more immediate organs of sense, or on some of the viscera contained within the great cavities. A few examples will readily indicate that set of cases which Esquirol denominates "illusions."

Illusions depending upon a Disturbance of the Organic Sensibility of the Encephalon.

CASE I.—A young lady, 18 years of age, having for some time suffered from a severe pain on the crown of the head, at length insisted that there was a worm within her head devouring her brain. No reasoning could disabuse her mind of this illusion; and she was convinced that the only method of relieving her was the extraction of the worm. An incision was accordingly made through the scalp, and a portion of fibrine was drawn out, with much ceremony, as if to corroborate the truth of her prediction. She was satisfied, and expressed great pleasure. The wound was kept open for two or three months, by which time not only all the pain, but the mental illusion as well, had entirely subsided.

CASE II.—A country woman was admitted into the Salpêtrière, in consequence of intense pain at the top of the head, which she attributed to the presence of some animal concealed under the skin. An incision was made through the scalp at the pained spot, and a portion of an earth-worm was then shewn to the patient, as if it had been extracted from the wound. She testified great joy at the time, being assured, she said, of her speedy recovery; but the hope of this fortunate event was soon baffled, for, in a fit of rage, she tore open the issue which had been established at the wound, and the mind became as unaltered as ever.

CASE III.—A lady, 30 years of age, who had fallen into a state of hypochondriasis, after suffering great mental distress, was impressed with the idea that her brain had become petrified. Some time after, she thought that it had softened, and was in a fluid state. On the dissection of this patient, a scrofulous deposit was found in the anterior lobe of the cerebrum.

Illusions depending upon a Disturbance of the Organic Sensibility of the Abdominal Viscera.

CASE I.—Ambrose Paré mentions the

case of a hypochondriac, who believed that he had some frogs in his stomach, and who was cured by a smart purgative or two, the attendants having cunningly introduced a frog or two into the night-stool before the patient went to it.

CASE II.—M. Esquirol examined the body of a woman who had died at the Salpêtrière; she had believed that some cruel animal was in her stomach. This viscus, at its pyloric orifice, was found cancerous.

CASE III.—In 1832, there was a woman in the Salpêtrière, who suffered from repeated attacks of severe colic. Her own idea was, that a regiment of soldiers lay concealed in her belly, and that she could feel them struggling and fighting with each other. Dissection shewed that a chronic peritonitis had existed for a length of time, and had glued large portions of the intestines together.

CASE IV.—A woman, 57 years of age, of a strong and sanguineous temperament, and so extremely devout and religious in her way, that she was styled by her keepers "la mère de l'église," because she was constantly talking of some scriptural subjects, was impressed with the belief that all the apostles and evangelists had taken up their residence within her bowels; moreover, that the Pope held his conclave there; and that, occasionally, even some of the Patriarchs of the Old Testament sojourned with his holiness. On examining the abdominal viscera of this woman after death, it was discovered that all the intestines had become agglutinated together, in consequence of chronic peritonitis.

CASE V.—Similar morbid appearances were found in the abdomen of a lunatic, who believed that a devil had taken up his abode in his stomach to torture him. In this case the skin, over almost every part of the body, was singularly insensible to mechanical injury; it might be pricked, pinched, and cut, without the patient appearing to suffer any pain.

Illusions depending upon a Disturbance of the Sensibility of the Generative Organs.

A woman, well advanced in years, was haunted with the idea that the devil had crept into her womb, and that nothing could dislodge him from his dark abode. This woman died, and it was found on dissection that there were several hydatids on the external surface of the uterus.

In another case, in which the patient believed that some venomous animal had entered her womb, and was accordingly in the habit of pushing pieces of meat up her vagina to entice it down, a similar disease was found affecting the uterus.

Such are a few examples illustrative of delusions which appear to take their origin from corporeal impressions, acting upon a disturbed mind. We mean not to enter into any investigation of this most abstruse subject: our only motive has been to afford some authentic data to the inquirer*.

COLLEGE OF SURGEONS.

THE subjoined notices have just been issued: we hasten to insert them, for the benefit of those to whom they apply.

NOTICE TO HOSPITAL SURGEONS.

Royal College of Surgeons in London,
28th Oct. 1834.

In order to verify the certificates presented by candidates for the Diploma of the College,—

The surgeons of all recognised hospitals are requested to transmit to the secretary, on the 1st of November, the 1st of February, the 1st of May, and the 1st of August in each year, or as soon after as possible, a quarterly return of the students attending the same, noting the dates of entry, and the periods for which they have entered, together with any remarks as to attendance, absence, &c., according to the form, herewith enclosed, and which will be furnished by the College on application to the secretary.

EDMUND BELFOUR, Sec.

A notice to the same effect as the preceding has been issued to Lecturers.

NOTICE TO SURGICAL STUDENTS.

Royal College of Surgeons in London,
28th Oct. 1834.

It is expected by the Council of the College, that the following regulation be attended to by all students coming to London for any part of their education, and with the ulterior view of becoming candidates for the Diploma of the College.

REGULATION.—Every student, on the commencement of his education in London, is desired to present himself at the College, to register his name, together with the documents of his previous studies; at which time he will be required to produce evidence, satisfactory to the Court of Examiners, of having entered to those studies which are necessary for the completion of his education; and credit will be given for attendance on hospital practice or lectures in London, only from the date of such registry.

EDMUND BELFOUR, Sec.

SIR JAMES EYRE.

On Thursday last, Sir James Eyre, of Margaret Street, Cavendish Square, was elected one of the accoucheurs to the St. George's and St. James's General Dispensary, in the room of Dr. Chowne, resigned.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, the 30th of October, 1834.

George Henry Perritt, London.
Frederick Beverly Dixon, Norwich.
John Stileman Bostock, Steyning.
Samuel Davie, Ipswich.
Thomas Lucas, Soham.
John Brookes Williams, Tethbury.
William Henry Smith, Kennington.
Richard Francis Salton, Steyning.
William Russell Dalton, Ipswich.
William Alexander Anderson, London.
Emanuel Baker, London.
John Currie, Bungay.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

—
LECTURE VI.

DISEASES OF THE LUNGS.

HAVING thus, gentlemen, completed the theory of the signs, we now proceed to the second section of this part of the course, or to the *diseases of the lungs*.

As I stated in the introductory lecture, I shall classify these diseases in an anatomical order; and as the respiratory organs consist of a trachea and its ramifications; of an accumulation of air-cells, constituting their proper substance, or parenchyma; and finally, of a fine serous investing membrane, called the pleura; so we shall successively describe their affections under the heads of, 1st, diseases of the trachea and bronchial tubes; 2d, diseases of the parenchymatous tissue; and 3d, diseases of the pleura. We follow here the arrangement of Laennec, which is simple and easily understood.

In speaking of each particular disease, we shall proceed invariably in the following order:—We commence with its morbid anatomy, constantly illustrating that part by preparations and drawings: there is a great advantage in this mode of proceeding, for you will at once become acquainted with the lesion of structure which really constitutes the disease, and you will soon find that the symptoms will thereby be easily understood, and even frequently anticipated. I know that this is not the ordinary method of teaching medicine, but

that the morbid anatomy, if described at all, is generally so, after the symptoms have been mentioned; but I have found from a tolerably long experience, both in my own studies, and in instructing others, that the plan I propose is most advantageous; indeed, it is impossible to understand the local signs of pulmonary and cardiac diseases without being previously acquainted with the organic lesions which occasion them.

After describing the morbid anatomy of the particular disease, we shall then proceed to the signs by which the alterations of structure are rendered evident to our senses; by shewing, 1st, the *functional signs*, or the signs afforded by the more or less altered state of the functions which the lungs perform. 2d, The *local signs*, or those which arise from a local examination of the organ. 3d, The *general signs*, or the signs which arise from changes of structure or function of one or more of the rest of the organs of the body, in consequence of the disease of the lungs.

We shall then consider the *causes*, dividing them into two classes; the first relating to the *individual*, as age, sex, temperament, idiosyncrasy, &c.; and the second, causes *external* to the individual, and acting upon him, as cold, moisture, miasmata, contagion, &c. I shall say but little upon what has been called the *proximate cause*, as that is a subject purely speculative, and we shall have but too little time as it is to describe well-authenticated facts, without entering into vague and useless hypotheses. We shall conclude the subject by pointing out the various indications of *treatment*.

DISEASES OF THE AERIAN PASSAGES.

You are aware, gentlemen, that the aerian passages are lined by a mucous membrane, and it is particularly to the state of this membrane that we must direct almost all your attention: we shall first consider its inflammation; 2dly, the dilatation of the bronchial tubes,—a disease first de-

disease proceeds; for, as the bland fluid is formed, whether it be of a white or yellow kind, the membrane diminishes in thickness and firmness. The inflammation diminishes as the secretion increases. This is the general morbid condition of the acrian passages; particular modifications we shall speak of previous to describing the signs of each species.

Symptoms; functional.—You are of course aware, gentlemen, that the air-passages consist not only of the larynx, trachea, and bronchial tubes, but also of the cavities of the nose, the mouth, and pharynx: all these parts are lined by the same mucous membrane, modified, it is true, but subject to the same inflammation; our account of catarrh would therefore be incomplete, were we not to describe the disease as affecting the whole of the surface of the membrane. I shall except merely that of the mouth.

A common function is performed by the air-passages, namely, the transmission of air to and from the lungs; but various other functions are also adapted to different portions of the acrian mucous membrane, consequently the functional signs vary according to the part affected. We shall describe the symptoms in the following order:—1st, of catarrh of the Schneiderian membrane; 2d, of the pharynx; 3d, of the larynx; 4th, of the trachea and bronchial tubes.

Inflammation of Schneiderian membrane, or coryza.—The difficulty of transmitting the air is in proportion to the swelling of the membrane of the nares: there is a general sense of fulness, uneasiness, oppression, and weight, referred to the nasal cavities, and more particularly to the bridge of the nose. If the disease, as is frequently the case, ascends into the frontal sinuses, the same sensations extend across the forehead, accompanied by more or less of cephalalgia; the membrane also lining the nasal ducts becomes swollen; the affection extends to the lachrymal sac—the tears can no longer penetrate the puncta, and they flow over the cheek; the conjunctiva often participates in the inflammation, and reddens. The sense of smell is of course disturbed, and the patient distinguishes odours with difficulty.

The membrane, as I have already described, is in the first instance dry, all secretion is suspended, and this dryness occasions an irritating, itching, and hot sensation, more particularly at the anterior opening of the nostrils. You will observe there, too, that the small hairs are covered by a fine white pulverulent deposit, from the absorption or evaporation of the thinner parts of the previously healthy secretion. Then follows the acrid fluid, which, flowing upon the upper lip and *alæ nasi*, ex-

corlates and irritates them. It often passes into the posterior part of the nares, distils, as it were, into the pharynx, upon the *rima glottidis* and *epiglottis*, and occasions a violent cough. However, this fluid soon changes in its character, and becomes bland; the cough then diminishes, the irritation subsides, and the transparent secretion gradually assumes a yellow puriform appearance, and at last nothing remains but inspissated mucus.

Inflammation of the mucous membrane of the fauces, or cynanche pharyngea, and tonsillar.—Coryza is sometimes followed by, or co-exists with, inflammation of the mucous membrane lining the fauces; but that is by no means invariably the case, for these inflammations may happen perfectly independently of each other. If the pharynx be attacked, you will see that its surface is of a bluish red colour, and the young practitioner is often alarmed from the darkness of the tinge, thinking it indicative of approaching gangrene, but it arises from a greater quantity of veins existing in that part than in any other portion of the mucous surface, and the colour of these veins shew through the membrane. The membrane is also swollen.

When, however, the anterior part of the fauces is affected, then the anatomical characters vary, in consequence of the *amygdalæ*, *velum*, and *uvula*, participating in the disease; you will then see that the redness is brighter and more vivid; that all the parts are more swollen; the *amygdalæ* enlarge, approach, and touch each other, leaving a small triangular space below, having the upper and back part of the tongue for the base of the triangle, and a similar space above, covered by the swollen *velum* and *uvula*: abscesses of the *amygdalæ* frequently form; the membrane lining the Eustachian tube and the salivary glands often also inflame.

The functional signs have here a reference to three offices which the fauces have to perform: 1st, to the transmission of air; but the swelling is rarely so great as to cause any serious impediment to its passage; when there is any dyspnoea, it in all probability arises from the disease having extended into the *rima glottidis*, although I do not deny that the *amygdalæ* may so enlarge as to lie over and obstruct that orifice; 2d, to the transmission of the food; and here the swelling and consequent pain occasion the greatest difficulty in swallowing, or *dysphagia*; 3d, to the passage of air into the tympanum: this function is frequently impeded, so that the patient becomes more or less deaf, and violent pains often shoot from the fauces in the direction of the Eustachian tube towards the ear; the salivary glands often inflame and swell also.

The succession of changes in the secretion is not so manifest in this case as in coryza: it is true that the inflamed surface is in the first instance dry, the acrid fluid then follows; but when it assumes the bland character, it remains pituitous, and does not become so distinctly yellow. The quantity is often considerable, and obstructs the fauces from its viscous character.

Inflammation of the mucous membrane of the larynx, or laryngitis.—When inflammation attacks the mucous membrane of the larynx, it is called *laryngitis*; the functional symptoms then vary considerably, according to the intensity of the disease: thus, it may appear in a moderate form, which is a very common affection, or an aggravated one, which is fortunately very rare.

Moderate form.—The functions of the larynx are to transmit the air and to form the primitive note of the voice, so that the signs under this head refer only to these two objects. The transmission of the air is rarely obstructed, because the mucous membrane of the larynx, or rima glottidis, is but slightly affected, consequently there is no dyspnoea, or it is but very slight; but the voice alters from the commencement: it is hoarse, broken, sometimes almost lost, or the patient speaks only in a whisper; in fact, this is the common hoarseness, or cold, so constantly met with during rapid variations of temperature.

The mucous membrane is in the first instance dry: a sensation of irritation, heat, and tickling in the throat, is the consequence, and a violent cough follows, and continues until a sufficient quantity of mucus is torn from the trachea and bronchial tubes to moisten and lubricate the inflamed parts: the uneasy sensations are repeated, the cough is renewed, and often continues so long that venous congestions threaten, the face swells and becomes blue, the eyes are turgid, and the cerebral functions momentarily confused, so as to threaten apoplexy: the whole circumference of the chest, particularly at the attachments of the diaphragm, becomes tender, sore, and tired, from the reiterated coughing.

The acrid secretion soon however forms, and the cough, if possible, becomes still more aggravated, in consequence of its irritating the edges of the rima glottidis; as, however, it changes into the bland, transparent, and viscous fluid, and from thence into the yellow or mucous, all irritation gradually ceases, the expectoration becomes loose and free, and the cough disappears, although the voice often remains hoarse for a considerable time.

It is generally observed that the cough is most troublesome at night, keeping the patient awake for hours, and you will al-

ways see it aggravated by suddenly changing the temperature; as, for instance, in passing from the cold air into a warm room, or from a warm room into the cold air.

Severe form, or acute laryngitis.—But when the inflammation of this part of the mucous membrane is still greater, then it forms one of the most formidable and dangerous diseases to which man is subject.

You will recollect, gentlemen, that the danger of all the affections of the air-passages depends upon the degree of narrowness of their tube or tubes, and the consequent diminution of the quantity of air sent into the lungs.

The morbid anatomy of this affection is the same as in the preceding species; it differs only in the greater intensity of the inflammation. The mucous membrane lining the rima and larynx is considerably swollen and reddened; there is frequently serous effusion into its submucous cellular tissue, from whence it has been called also *oedema glottidis*: it is probable that even the cartilages participate in the inflammation. The same series of secretions occurs also here; and occasionally, although I think very rarely, abscess forms.

The epiglottis, in all the cases I have seen, is involved in the disease; its membrane reddens and swells; and the whole valve becomes erect, and is depressed with difficulty in the act of swallowing. In these preparations, you see, gentlemen, very distinctly the appearance which the rima, larynx, and epiglottis, put on in this disease.

Signs.—The functional signs have a reference to the voice, to deglutition, to coughing, and to respiration.

The voice soon becomes hoarse, descends into a whisper, and is finally, in extreme cases, totally lost. The power of deglutition is often considerably impeded: this happens from the inflammation occasionally attacking the œsophageal face of the arytenoid cartilages, and also from the difficulty of depressing the erect and inflamed epiglottis. This latter circumstance is of great importance to attend to, as the history of the two cases from which these preparations were obtained will sufficiently exemplify. The one is the larynx of a student at St. Bartholomew's Hospital. You see its inflamed state, and particularly that the epiglottis is thickened, erect, and of diminished elasticity. You know that the function of the epiglottis is to act as a valve in closing the rima during the act of deglutition; so that the food shall not pass into the larynx, but in the inflamed and inelastic state this function can be but imperfectly performed. In this case an ordinary purgative draught was given to the patient,

who, endeavouring to swallow it at once, was suffocated by the effort. You see, gentlemen, that the epiglottis could hardly have acted as a valve here, and the fluid consequently entered into the narrow orifice of the larynx. The second case, which is of this preparation, was very similar to the first. You perceive here also the great swelling and redness of the different parts of the larynx, and of the epiglottis. This case, as you may suppose, presented all the symptoms of acute laryngitis. The patient had been most boldly treated by his medical attendant; but the symptoms became aggravated; and I determined, if a very extensive mercurial friction did not produce a good effect in a few hours, to propose the operation of bronchotomy. The wife of the patient was told of her husband's dangerous position: she pressed him to settle his affairs, and he became, for the first time, aware of his peril. He by signs, insisted upon having some porter brought to him; he took a copious and hasty draught of it, threw himself violently upon his back, struggled, and expired.

The cough is often not so violent in the acute form of laryngitis as in the moderate; but the state of the respiration demands our utmost and most anxious attention.

As the disease progresses, the mucous membrane of the larynx becomes highly swollen; the orifice of the rima glottidis is narrowed to such a degree, that the purposes of life cannot be effected by the diminished column of air which passes through it: nature, however, makes a strong effort; she accelerates the movement; the respiratory muscles are thrown into rapid action, constituting dyspnoea from this cause. As the rima still becomes narrower, the difficulty of breathing increases; a violent burning pain, or suffocating sensation, is felt at the pottum Adami; the voice, which from the beginning was hoarse, is now lost; the air, in passing through the narrow orifice, produces a sound as if it passed through a brazen tube; the face becomes livid, the eyes red; the patient is erect; he manifests the most unceasing anxiety and jactitation; points to his throat as the seat of all his distress; and dies, sometimes overpowered and exhausted from his exertions; at other times, especially if strong and robust, in a desperate and convulsive struggle, as if under the bow-string of the executioner.

Inflammation of the mucous membrane of the bronchial tubes.—Having described these affections, we shall proceed to the disease as it affects the bronchial tubes.

When inflammation attacks the mucous

membrane lining the trachea and bronchial tubes, the functional signs must have relation to the passage of the air only. There will be difficulty of breathing in this case, proportionate to the degree of swelling, and to the extent of the tubes affected. If only a single tube be inflamed, the dyspnoea will not be great; if it occupy the whole of the tubes on one side, then the difficulty of breathing would be considerable; if it attack both lungs it is often fatal. There is a feeling of tightness and oppression across the chest, and a burning sensation, often referred to the sternum and cough. In the first instance, the cough is dry, because the membrane is dry; then the secretion will become acrid, but very soon it becomes bland; it increases in quantity, and finally assumes the yellow colour, characterizing the species; the cough becomes looser, the expectoration free, and all the symptoms gradually subside.

Local signs.—The local signs of inflammation of the aerian mucous membrane are sufficiently evident, whilst the disease exists in the cavities of the nose or pharynx. The appearances described under the head of morbid anatomy constitute these signs: thus in coryza, the swelling of the membrane, its redness, firmness, and its series of secretions; in cynanche, pharyngea, and tonsillaris, the swelling, the redness of the different parts, and the secretions also, are so many local signs; but, independently of these, the symptoms arising out of the lesions of their different functions would be sufficiently indicative of these affections. When the inflammation attacks the larynx, the altered condition of that organ cannot be seen, and local signs do not properly exist, and we are obliged to depend upon those arising from the derangements of its functions of forming the voice and transmitting the air.

But when the affection descends into the trachea and bronchial tubes, not only we cannot see the condition of the membrane, by which to obtain local signs; but as the functions of these tubes are now so simplified as to be mere conduits of air, so the only sign we can obtain arises from the lesion of that function or dyspnoea. It is true there is also cough and expectoration; they are, however, common to various other affections of the lungs, and are consequently not diagnostic.

Dyspnoea is common to every affection of the lungs and heart, when arrived at a certain intensity. By it alone, therefore, we cannot determine the nature of the specific lesion.

One of the most brilliant discoveries of Laennec was that of a series of local signs, by which catarrhal inflammation of

the bronchial tubes is rendered almost as evident as any external disease of the body. We now proceed to describe them.

This inflammation has for its consequences a swelling of the mucous membrane of the bronchial tubes, and a series of secretions: the local signs, then, have a reference to these two conditions.

Absence of Respiratory Murmur.—When the mucous membrane is considerably swollen, it may completely obturate the tube affected: the consequence must be that the respiratory murmur cannot be heard in that portion of the lung which the tube supplies, since no air can pass the obstructed point; so that it frequently happens, especially in severe catarrhs, that the respiratory murmur is absent in various portions of the lungs, but as this absence of sound is common to several other affections of that organ, we call percussion to our aid; and by striking the chest, we find that the sound elicited is natural in catarrhs, whilst, in almost every other affection of the lungs, it is dull, when there is no respiratory murmur. The reason of this difference is, that in catarrh the cells are filled with air, which the obstruction confines and prevents the renewal of, and consequently occasions a good sound on percussion, although the murmur be lost; whilst, in other affections attended by absence of the respiratory murmur, the air-cells are impermeable, either from their consolidation or compression, and then the sound on percussion is invariably dull and fleshy.

Rhonchus Sibilans, or Sibilating Wheezing.—If the membrane be less swollen, and the bronchial tube not completely obturated, then the sibilating sound is heard. I refer you, for its characters, to the lecture on Auscultation. As I there observed, it consists of a distinct whistle, sometimes a chirruping, or it is like the clicking of a small valve. With this sound, the respiratory murmur is always indistinct at the part affected, because of the diminished calibre of the tube.

Rhonchus Sonorus Gravis, or deep Sonorous Wheezing.—It has long appeared evident to me, that as the swelling of the membrane diminishes, this sound appears. It is loud, extremely distinct, like the rough scraping of the bass note of a violoncello by an inexperienced hand, or it is similar to the cooing of a dove; and its intensity is sufficient to cause a vibration upon the parietes of the chest, distinguishable by the hand. The respiratory murmur now becomes more distinct, evincing that the bronchial tubes are more patent; finally, the deep sonorous wheeze assumes a still deeper bass, merges into the respiratory murmur, mixes with it, and gives it a roughness, which I have designated *rough respiration*.

Rhonchus Mucosus, or Mucous Rattle.—The mucous rattle, or wheeze, occurs when the secretion appears, and is loud and noisy in proportion to the quantity of fluid thrown out. This sound, when it is formed in the trachea, can be heard through the medium of the air alone; but the application of the stethoscope, or the ear, to the surface of the chest, is necessary when it is formed in the bronchial tubes.

It frequently happens that viscous and tenacious secretions will adhere with sufficient force to obstruct the tubes, and occasion absence of the respiratory murmur, sibilation, or the deep sonorous wheezing; so that it would appear to be difficult to determine whether they depended upon the presence of secretions or a thickened state of the membranes: this difficulty is easily solved, by directing the patient to respire strongly, or to cough; then the air will be driven with sufficient force to remove the obstructing mucus, and the sounds will cease; the respiratory murmur will appear after a few efforts. If the sounds be occasioned by thickened membrane they will be permanent.

In examining these sounds, you must not expect to find them always precisely similar to the analogies I have presented to you: I have described only the exquisitely marked ones; for as the mucous membrane may be thickened in various degrees and in various parts—as the secretions vary in quantity and tenacity—so many modifications of these wheezings occur; but I assure you, gentlemen, a very little practice will render them perfectly easy to distinguish.

It is hardly necessary to speak of the value of these local signs; by them you can decide at once whether the disease in question be catarrh or not; you can determine the extent of the affection; for sometimes the wheezing may be heard only in a single line, as if in the direction of a single bronchial tube; sometimes it is heard all over one lung, occasionally over both. By judging of the distance of the sound from the ear, you can tell whether the tube affected be in the centre of the organ or at its superficies; you become aware of the intensity of the inflammation by the nature of the sound, and of its variation in different parts, by the variation of the wheezing. Thus there may be sibilation in one part, deep sonorous wheezing in another, mucous rattle in a third, or they may be intermingled. All this may appear to you now subtle and difficult; but there is not a more distinguishing organ than the ear, and I repeat my assurances that these difficulties exist only in the apprehension; even if they were greater, the subject is so important that you are bound to overcome them.

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

III.—On Inflammatory Enlargement of Bone, Abscess, and Necrosis.

THE bones are very liable to inflammation, which presents different features according to the kind of bone attacked, and to the state of the constitution which attends or produces it.

When a cylindrical bone (either the shaft or the articular extremities, excluding the immediate articular surface) is inflamed, in a person of unimpaired constitution, it often passes into conditions which are comparatively wholesome, and from which the step to restoration is direct. These conditions are, inflammatory enlargement of the bone, abscess, necrosis.

But when the articular aspect (that is, the surface to which the articular cartilage adheres) of a cylindrical bone, or when a round or flat bone, is inflamed, a different consequence ensues—the bone becomes *curious*. The same result ordinarily follows in any bone, if the inflammation proceeds from vice of the constitution, as struma, or taint in the habit, as syphilis.

In the present lecture, the first of the two cases which have been specified will be considered.

Simple inflammation of cylindrical bones is ordinarily characterized by the slowness of its march. It is attended with swelling, pain, and tenderness of the bone affected. It may be confined to the surface of a bone, or occupy the cortex, or extend into, or originate in, the cancellous structure.

a. Inflammation of the external surface of a bone is not separable from inflammation of the periosteum. The two parts are so intimately united, that increase of vascular action in the one necessarily extends itself to the other. Superficial inflammation of bone may be produced by a blow. If the inflammation does not speedily subside, it leads to the formation of an irregular and vascular growth of bone beneath the periosteum, which becomes at the same time more or less thickened. There is an injected specimen of superficial inflammation of the head of the tibia, corresponding with this description, in our museum. The tibia is more frequently inflamed than any other bone in the frame. Its dependent situation, which is against the free return of the blood, the extent of

its subcutaneous surface, which renders it sensible to changes of temperature, its place and office in locomotion, which expose it to be frequently struck, account for this. After the tibia, the femur is, as commonly as any other bone, the seat of simple inflammation.

The principles of local treatment applicable to this affection are the following. A dependent position of the inflamed bone is to be avoided. If the bone is well covered with flesh, like the femur, exciting action upon the surface of the limb by issues, setons, blisters, diverts the inflammation. If the bone is close below the skin, like the tibia, local abstraction of blood, and the relaxation of the periosteum by warmth and moisture, are to be employed; when the pain is intolerable, an incision down to the bone gives relief, by lessening the tension of the inflamed membrane.

Simple inflammatory enlargements of bone frequently result from general disturbance of the health. In that case more than one bone is usually affected. It is extraordinary what various appearances are found in bones thus thickened by inflammation. In some the thickening is a more or less solid deposition of bone upon the cortex, which preserves its distinctness from the superadded growth; in others the enlargement distinctly consists in an expansion of the cortex, in the middle of which a cancellous structure appears to have developed itself; in others (a progressive state from that last described), the thickened cortex is nearly solidified. The thickening and these appearances are commonly met with on one aspect of a bone, occupying a third, or half, of its length. In connexion with the two last, the medullary cavity is found sometimes in its natural state, sometimes encroached upon by an inward expansion of the crust. Sometimes, in combination with cortical enlargement, the greater part of the cancellous structure is solidified.

The rationale of these various appearances is easily understood when we call to mind the structure of a healthy cylindrical bone. In the fabric of such a bone there is no essential distinction of texture. The cortical part differs from the medullary in this alone, that its cells are finer, their walls thicker. When a dried bone has been broken transversely, if the fractured surface is examined with a magnifying glass, the transition from the lightest cancellous structure to the densest part of the shell is seen to be perfectly gradual, the channels only becoming narrower, and the partitions stronger. All the varieties of inflammatory enlargement are either expansion of the cells and channels in bone, or thickening of their walls—at one pe-

riod the first process, at another the second, predominating.

In simultaneous inflammations of several bones, the indications are to soothe the local pain, to set right every disordered function, and to discover in the history of the patient, and to correct, any peculiarity that may exist either of original diathesis, or habit superinduced by mode of life, by former disease, or by medicine administered for it.

A young gentleman, through a severe course of study for academical honours, fell into a state of extreme dyspepsia, attended with pain in the head, and inability to collect his thoughts. At the same time three or four of his ribs on each side enlarged and were painful. He gave up his studies and went to the south of Europe, where he entirely recovered. A year or two afterwards he became my pupil, and began the study of medicine in London. After a little time his former symptoms returned, and I saw him in a state approaching to hypochondriasis, with the singular addition of painful swelling of the ribs. Upon going into the country he recovered.

There are specimens in our museum, the history of which I could not obtain. They consist of the bones of the head, the humerus, and femur, from the same subject. These bones are each greatly enlarged; the cranial bones and the lower jaw to three times their natural thickness; the whole of the shaft of the femur, and the lower half of the humerus, to the same extent. They are very light, yet of a close but perfectly spongy texture, the cortical part having entirely disappeared. I suppose that this appearance is a result of inflammation.

b. When inflammatory action has gone on for some time in bone, it is liable to produce abscess. The most precise information that we have upon this subject, is in a paper by Sir Benjamin Brodie, in the seventeenth volume of the *Medico-Chirurgical Transactions*. Sir B. Brodie describes three cases of this affection, in each of which it occurred in the tibia—twice in the lower, once in its upper end. The ages of the patients were 24, 23, and 34. In each case the bone had been diseased, with great suffering, for several years. In the first case, the state of the bone, when examined after amputation, is thus described:—

“The whole of the lower extremity of the tibia was harder and more compact than under ordinary circumstances, in consequence, as it appeared, of some deposit of bone in the cancellous structure; and in its centre, about one-third of an inch above the ankle, there was a cavity, of the

size of an ordinary walnut, filled with a dark-coloured pus. The bone immediately surrounding this cavity was distinguished from that in the neighbourhood by its being of a whiter colour and of a still harder texture; and the inner surface of the cavity presented an appearance of high vascularity. The ankle-joint was free from disease.”

In the second case, Sir Benjamin Brodie was led, by its similarity to the first, to suspect the real nature of the disease; he therefore trephined the bone at a spot two inches below the knee, to which the pain was particularly referred, and then, by means of a chisel, removed several other small portions of bone at the bottom of the cavity made by the trephine. At this part of the operation, the patient suddenly experienced a sensation which he afterwards described as similar to that which is produced by touching the cavity of a carious tooth, but much more severe; and immediately about two drachms of dark-coloured pus issued slowly from the part to which the chisel had been last applied. From this instant the peculiar pain belonging to the disease entirely ceased, and it has never returned; the patient being able to walk in three months after the operation, and the wound being completely cicatrized in six.

The early history of this case is an instructive comment on some of the remarks which have been before made. Two years before the operation above described, the patient applied for advice; having then suffered for ten years with slight enlargement and pain in the upper extremity of the tibia. The swelling now occupied about a third of the length of the bone, and the patient complained of excessive pain, which disturbed his rest at night: some parts of the swelling were tender to the touch. On the supposition that the disorder was chronic periostitis, the following method was adopted:—An incision was made longitudinally on the anterior and inner part of the tibia, extending from the knee four inches downwards, and penetrating through the periosteum into the substance of the bone. The periosteum was found considerably thickened, and the new bone, which had been deposited beneath, was soft and vascular. The immediate effect of the operation was to relieve the pain which the patient suffered. The wound gradually healed, and it was for some time supposed that a perfect cure had been accomplished. The enlargement of the upper extremity of the tibia, however, never entirely subsided. In a year and a half, pain was again experienced in it, which in five months became constant, but more severe at one time than

another, often preventing sleep during several successive nights. The enlargement of the tibia was as great as before, and the skin covering it was tense, and adhered more closely than is natural to the surface of the bone.

There is a preparation in our museum, of abscess in the lower end of the tibia, which corresponds very closely with that described in the first of the two cases which I have cited. The cavity of the abscess is lined with a highly vascular membrane; the cancellous structure around is very much condensed, but is not as compact as the cortical texture of ordinary bone.

The patient was a young woman who was under my care in the Middlesex Hospital: she had suffered eleven years with enlargement and pain in the tibia, for which, some months before, she had been under treatment, and had left the hospital relieved. She returned in a state of aggravated suffering. With the knowledge of the cases which I have described, I thought it probable that there was abscess in the bone. But there were reasons which induced me to amputate the limb in preference to using the trephine. The disease had commenced in the upper part of the tibia, and had involved the knee-joint, which had become ankylosed at an inconvenient degree of flexion. The lower two-thirds of the tibia were enlarged, and involved in the present disease [as it turned out, a second small abscess existed in the middle of the shaft of the bone]; the whole limb was greatly extenuated, and the patient was in very delicate health,

from long-continued suffering. She recovered.

Another specimen of abscess in bone, which is represented in the adjoining figure, was given to me by Mr. Arnott. It was situated in the middle of the femur. The cancellous structure around it had become nearly consolidated. The abscess was found unexpectedly, on making a section of the femur after the patient's death. The symptoms belonging to it had been masked by disease of the joint, which had supervened upon the extraction of a loose cartilage from the knee, and had rendered amputation necessary.

c. Mortification is the term used to denote the death of soft parts—*necrosis*, that of bone. Inflammation of the soft parts occasionally terminates in their death. In like manner, inflammation of bone sometimes terminates in necrosis.

A child, between three and four years of age, was seized with an inflammatory swelling of the leg, attended with considerable symptomatic fever. By the use of the ordinary remedies the symptoms were mitigated; but, in three weeks, a deep-seated abscess was distinguishable, which was opened. The child recovered its health, but the enlargement of the leg continued, and a sinus remained where the abscess had been punctured. At the expiration of a year, a piece of bone projected at the opening, which, when I drew it out, proved to be the cortex of the shaft of the fibula. It is to be observed, however, that necrosis does not in general commence with the acute seizure described in the preceding case; and that neither does the dead bone which comes away usually present those appearances which continued inflammation produces.

Death of a part, or of the whole, of the shaft of a long bone, is liable to occur from childhood to the age of twenty or twenty-five, or even to a later period. The tibia, femur, lower-jaw, humerus, fibula, radius, and ulna, are the bones most commonly so affected.

When the shaft of a long bone is necrosed, a salutary process is immediately set on foot, which comprehends three objects: the first is the separation of the dead part, or *sequestrum*; the second, the formation of a temporary bone, to serve while the separation of the sequestrum is in progress; the third, the final restoration of a portion of bone, accurately resembling that which has perished.

1. The detachment of the sequestrum is effected partly by the removal of the contiguous layer of living substance—this is proved by the entire and uninjured surface which the greater part of the sequestrum exhibits; partly by the superficial absorp-

tion of the dead bone itself, through the agency of the living textures in contact with it. The last observation is presumed to be correct, from the excavated and honey-combed surface which a part of the sequestrum generally presents. At the same time, it must be admitted that this appearance may result from the bone having died to that extent only, leaving (which, no doubt, sometimes happens) a partial thin crust of bone living. Mr. Wilson gives a curious proof that the living tissues in contact with a bone can operate its partial absorption. Adverting to the practice of transplanting teeth, which existed in his time, he observes that the teeth used to adhere at first, but that they seldom remained in their new sockets more than three or four years: several such teeth, which he examined, had lost their fangs by absorption.

2. The temporary new bone is formed around the dead. The dead bone irritates the surrounding tissues, which, while they shrink from it, thicken and give origin to a callus; that ossifying, as in fracture, forms an irregular shell of porous bone, enclosing the sequestrum. In this irregular shell, holes are either left, or wrought by absorption, which communicate by means of sinuses with the surface of the limb; these holes and sinuses in the common order of phenomena are the channels through which the sequestrum finally makes its exit. The art of the surgeon is directed to accelerate the removal of the dead bone, by making convenient apertures in the shell, as soon as ever the sequestrum is loosened.

3. No sooner is the sequestrum removed, than a growth from the cancellous structure of the ends of the bone and from the interior of the temporary shell, takes place, and fills the vacant cavity; at the same time the temporary shell of bone contracts in volume by a process of modelling absorption and deposition, and becomes smooth upon its surface, being destined finally to assume the exact structure of the bone which has been lost.

In the ordinary course of a necrosis of the shaft of a cylindrical bone, it appears to be the cortical part alone which dies; at all events the cortical part alone comes away as sequestrum. The cancellous structure, which it enclosed, whether then dead or living, is absorbed wholly, or in great part, before the sequestrum becomes detached. One may suppose that it does not die, for two reasons—first, the cancellous structure has a much greater force of vitality than the cortex, and might be expected to survive what would destroy the latter; secondly, if the cancellous structure die with the cortical part, where is the agent which removes it?

The process of death, with subsequent

reparation, which has been described, is common in the shafts of the long bones, and is rarely excited elsewhere; something like it, however, has taken place in the lower jaw, and is stated to have partially occurred after necrosis of the scapula.

Necrosis, without reparation, may take place of the articular ends of long bones. There is a specimen in our museum of nearly half the outer condyle (in a diseased knee which I amputated) necrosed, and in process of separating; and another, in which a portion of the condyles of the humerus is in the same state. In these instances, any attempt at restoration is prevented by the disease occasioned in the contiguous joint.

Necrosis of the cuboid bones, for the same reason, is unattended with reparation.

Necrosis of the cranial bones is followed by that meagre reparation only, which has already been described in treating of their fracture. There is in our museum nearly the whole of a parietal bone, which came away from a patient under my care in the Middlesex Hospital. It was detached in five months. No cerebral symptoms occurred during the process.

The term *exfoliation* is often employed to denote the separation of dead bone. There is, however, something very capricious in its use: it is seldom applied to the separation of a sequestrum, but in every other case it is used. Thus, it is applicable to the preceding instance, in which the whole thickness of the parietal bone *exfoliated*; and in like manner to that separation of a segment of a long bone (from the narrowest rim to four, six, or even eight inches of the shaft), which sometimes follows an amputation.

The term *exfoliation* perhaps is used with most propriety when applied to the separation of a surface only.

The surfaces of bones have their vitality readily destroyed. A blow upon the cranium, or upon the tibia, which strips the bone of its periosteum, is often followed by this consequence. In a young person, however, the bone will often recover, unless considerable violence has been done to it. The denuded surface, instead of becoming dry and white, in four or five days assumes a light red tint, which gradually deepens; then pouring out a gelatinous exudation, it becomes covered with organized and florid granulations. The same appearance is seen in the healing of a healthy stump that has not united by adhesion: the cut end of the bone, after a fortnight, is covered with its own growth of granulations.

The inspection of such a stump at this period explains the process of reparation in *compound fractures*; that is to say, in fractures which communicate with an external wound. In a compound fracture which

goes on wholesomely after the first inflammation, the whole internal surface of the wound presents an uniformly granulating surface of rapid growth, which fills up its cavity. In this growth of granulations, cartilage is formed, which constitutes a callus, that ossifies there, as in simple fracture, only with more assistance perhaps from the vessels of the bone itself.

When a portion of the entire thickness of the crust of a cylindrical bone is necrosed through external injury, and remains denuded, it does not come away as a sequestrum, but exfoliates; the process of reparation which then takes place is *from within*, and consists in a thickening and expansion of the adjacent cancellous structure. I have seen the same process set on foot after necrosis of part of the subcutaneous shell of the tibia following inflammation.

MEDICO-LEGAL DISINTERMENTS IN FRANCE AND ENGLAND.

*From an Introductory Lecture delivered at the
Aldersgate-Street Medical School Nov. 1, 1834.*

BY DR. CUMMIN.

[HAVING noticed the very unsatisfactory figure made by Mr. Hunter, as a medical witness, at the trial of Donellan for the poisoning of Sir Theodosius Boughton, the lecturer proceeded—]

The trial just spoken of was remarkable for another circumstance, to which I am desirous of drawing your attention. Evidence was given in this case as to the appearances observed on a medico-legal disinterment. The body of Sir Theodosius Boughton was taken from the grave on the *eleventh day* after death, and examined with a view to detect the marks of poison. The description given of the appearances by Dr. Rattray is curious:—"The body appeared swollen generally; the face was of a round figure, extremely black." This, by the way, corresponds with the observation made by Sir Henry Hallford, in a paper read not long since at the College of Physicians: Sir Henry mentioned that he was present at the examination of Sir Theodosius Boughton's body, and that the face resembled "a pickled walnut." But to return:—"The lips were swelled and retracted, shewing the gums; the teeth were discoloured; the tongue protruded beyond the teeth, and turned up towards the nose. The blackness diminished as it descended towards the breast. The remainder of the body was spotted in several parts." Yet this was an appearance (the blackness con-

finued to the head and upper part of the chest) in which Mr. Hunter—in his great zeal for the prisoner's safety—said he could see nothing but the effect of putrefaction. Dr. Rattray, however, distinctly deposed to having observed the same appearance in the body on the third or fourth day after death.

I shall not trouble you with further details of the evidence given on this occasion; suffice it to say, that they were listened to with great attention by a crowded court, and contributed strongly, in conjunction with the other circumstantial evidence of the case, to convict the prisoner. My purpose in saying so much on the subject is to endeavour to shew you that the duties of the medico-legal practitioner are often very curiously diversified; and that, even were there no provision for legal medicine as a distinct study—as was the case in this country at the date of the trial in question, and for many years after—still events will from time to time occur, rendering it imperative on the practitioner to undertake some of the most difficult investigations. And among those difficulties, none are perhaps more likely to tax his ingenuity than medico-legal disinterments.

What extraordinary things have been achieved in France of late years, by exploring the secrets of the grave, are sufficiently celebrated. Those achievements constitute almost a new era in legal medicine, and confer a triumph on medical science. The murderer has been discovered; the mutilated, perishing, and nearly evanescent remains of his victim, have been made to give their evidence against him; the poison that deprived the victim of life has been rendered up grain for grain; the wound that dispatched him has remained to give its awful testimony years after.

It is in France chiefly that this subject has been considered in all its bearings, and carried to a state of high perfection, both by experiment and actual practice. Orfila has particularly distinguished himself by his researches in this respect; his work on *Juridical Exhumations* is as ingenious as it is singular. In it he enters deeply into the examination of the physical changes which the various tissues of the body undergo, according to the length of time elapsed up to the period of investigation—whether the parts have been deposited in earth, water, or other enveloping substances; and with especial reference to forensic medicine, he shews how examinations of this kind may be made to elucidate obscurities relative to poisoning, wounds, infanticide, the determination of sex, age, stature, and every thing that can indicate identity. He has, besides, di-

vested the process of much of its terrors. He has demonstrated that, with certain simple precautions, there is no danger in examining a body at any period subsequent to interment. It was the general impression up to his time that there was; but now, however forbidding, in the eyes of persons not accustomed to such things, the duty of the examiner may appear, no medical man will look with aversion on the task—at least none who has made himself but moderately acquainted with the duties that devolve upon him; he will, on the contrary, seize the opportunity when it offers, of at once promoting science, and benefitting the community by his labours.

In the drawings which are before you, you have copies of the appearances which presented themselves to Orfila and Lesueur, in their experimental investigations.

[Some drawings of persons disinterred at different times were here exhibited and described.]

I shall give a few examples of what may be effected by researches of this kind. Not long ago proofs of poisoning were discovered in the remains of a body that had lain in the earth for *seven years*. The case occurred at Lyons. A woman had long been suspected of having poisoned her father; but for want of direct proof, justice could not reach her. At length a circumstance occurred which threw a strong light upon her guilt; and though seven years had elapsed, it was thought requisite and proper to disinter the body. The examination and the necessary experiments were conducted by M. Ozanam, assisted by M. Ide; and complete evidence of the presence of arsenic among the shapeless tissues of the stomach was obtained.

There was a very singular case investigated in Paris during the last year. I allude to that in which the remains of a murdered female were disinterred, identified, and the mode of death ascertained, after a lapse of *eleven years*. Little more than a heap of bones was found; but from their position, condition, and several peculiarities, the reporters (among whom we find the names of Orfila, Barruel, Chevalier, and Boys de Loury) were enabled to come to the following conclusions:—1. That those were the bones of a human skeleton; 2. of a female; 3. the age from 60 to 70; 4. the stature about five English feet; 5. the hair had been bright blond, but latterly was mixed with grey; 6. the deceased had died of strangulation—the act being homicidal; and 7. the remains had lain in the earth for several years.

The prisoners, who had long been suspected of the murder, were tried and condemned to the galleys for life—having had a narrow escape of the guillotine.

It may be perhaps curious, and not uninteresting, to you, to be reminded of certain disinterments which have taken place in this country for medico-legal purposes: we have some very remarkable ones on record. As a counterpart, and a sort of contrast to the last case, let me call your attention to what occurred in the year 1758, at Knaresborough, in Yorkshire. I allude to the celebrated case of Eugene Aram, around whose history the pen of the novelist has recently thrown so much attraction; but whose plain unvarnished story is in itself, independent of any collateral fiction, almost a romance. This highly-gifted but unfortunate person, instigated by penury, and jealousy, as it is said, but, above all, by the instigation of a depraved and profligate companion, committed a murder on one Daniel Clarke; and it was not till *fourteen years* after that proof of the crime was procured: that proof was the skeleton of the victim. Suspicion had never been attached to the name of Aram, but the desperate Houseman was long supposed to have been the assassin. At length, a skeleton being found accidentally, in a field at Thistlehill, near Knaresborough, it was thought to be Clarke's, and Houseman was examined at the inquest. He was much confused and conscience-stricken on the occasion; but affecting a degree of levity which had just the contrary effect to what he intended, he took up one of the bones, and said, "This is no more Clarke's bone than it is my bone." Upon which he was immediately questioned as to where Clarke's bones were; for he had now as good as confessed that he knew. He turned king's evidence—denounced Aram as the murderer—admitted that he had been an accomplice, and described exactly where the true skeleton would be found. In St. Robert's Cave, he said, they would find it, "just by the entrance, and with the head turned towards the right."

On the trial, *the skull* was produced in court—a ghastly witness against the accused. On the left side of it there was a fracture, that, from its nature, could not have been made but by the stroke of some blunt instrument; the piece was beaten inwards, and could not be replaced but from within. Mr. Locock, the surgeon, who was the chief, if not the sole, medical witness examined as to the appearances, gave it as his opinion, "that no such breach as that pointed out in the skull could have proceeded from natural decay—that it was not a recent fracture by the instrument with which it was dug up, but seemed to be of many years' standing." This seems to have been about the amount

of the evidence which, taken with the circumstantial detail given by Houseman and some other witnesses, operated in procuring the prisoner's conviction: if, indeed, Aram did not himself do more to that end, by the extraordinary and truly surprising defence which he made—at once singular for its eloquence and its learning. This, I may remark, was the opinion of the celebrated Dr. Paley, who happened to be present at the trial. Many years afterwards, when conversing with some friends, about certain lives in the *Biographia Britannica*, which somebody observed were those of obscure individuals—Eugene Aram's, for instance. "Nay," said Paley, "a man that has been hanged has some pretensions to notoriety, and especially a man who has got himself hanged by his own cleverness, which Eugene Aram certainly did."

Aram called no witness for the defence. He relied wholly on his own ingenuity, and produced, certainly, most powerful arguments to shew that the bones discovered were those of some hermit, who had in former times dwelt in the cave; and he mentioned several caves similar to St. Robert's, in which human bones had been found. When we recollect that it is the great principle of our law, that no man can be condemned for murder unless the body of the person supposed to have been murdered be found and identified, we must at once admit the importance of the line of argument taken up by the accused.

The identity, in fact, of the skeleton was not made out: so far from its being proved to be Clarke's, it was not even shewn to be that of a man; the sex was not proved—nor the age—nor, in short, any of the numerous points which, no doubt, would be elicited were the examination instituted at the present day. All that was ascertained was, that here was a human skeleton found as directed to be sought for by a wretch who had given information in expectation of pardon for his crimes. Why might it not be wholly a plot of Houseman's, to get rid of the unfortunate Aram? He might have buried the bones there himself, or found them buried when digging in the cave, perhaps, for the concealment of plunder.

Let it not be thought that I am of the number of those who hold Aram to have been guiltless. The man is said to have confessed his crime before his execution. But my object in dwelling on the circumstances is to shew the very insufficient circumstantial testimony on which the prisoner's life was forfeited, under the semblance of law and justice. The truth seems to be (as Paley said, and as now seems generally admitted), that Aram was chiefly indebted to his own eloquence and cleverness for the forfeiture of his life.

About the close of the seventeenth century occurred the deeply interesting trial of Mr. (afterwards Judge) Cowper, for the murder of a young Quaker lady. There can at present be little doubt but that the deceased drowned herself in a fit of disappointed love: at the trial, however, and for a long time after, much contrariety of opinion prevailed as to the question, whether she was simply drowned, or murdered first and thrown into the river afterwards. The evidence for and against the prisoner was chiefly derived from the appearances of the body disinterred *six weeks* after burial. No water was found in the stomach or lungs—a fact deemed conclusive by one party that the lady *could not* have been drowned; but competent witnesses on the other side—among whom were Garth, Sir Hans Sloane, and Cowper the celebrated anatomist—shewed, according to a more correct pathology, that the introduction of water into the cavities on submersion is purely accidental, and that there were appearances enough in this case to indicate suicidal drowning. The lungs, stomach, and abdominal viscera, I may add, were found perfectly sound at the time of the medico-legal examination.

In the year 1828 there was another remarkable case, in which the chief evidence for the prosecution was derived from a medico-legal disinterment. You will probably remember the circumstances of the trial of Corder, for the murder of Maria Martin. The body of the victim was found buried in a barn, where it had lain for *eleven months*. On the trial, Mr. Lawton, the surgeon, stated, that he first saw the body in the hole where it was discovered. It was much decomposed, and had the appearance of having been buried for nine or ten months at least. He then described the dress, and gave so many particulars relative to what he observed, that the deceased was completely identified and the manner of her death exactly made out. A handkerchief was found tied tightly round the neck, forming a groove. In the neck there was also the mark of a perpendicular stab, about an inch and a half in breadth, extending deep into the neck. There was an appearance of injury to the right eye, and the right side of the face; it seemed as if something had passed in at the left side, through the cheek, removing the two last grinders, and then out at the right orbit. This was apparently done by a pistol ball. The lungs and chest were also examined, and there was found a wound between the fifth and sixth ribs, penetrating into the substance of the heart. This was effected by a sword, which was produced.

The sword was identified in court by the cutler who had sharpened it for Corder; and the head of Maria Martin was also identified, chiefly by the loss of a tooth in the upper and lower jaw. The observations made in the lungs, too, were important; there were adhesions of the pleura, and other marks, by which it appeared that the deceased had had cough and pain of the chest not long before death,—which was precisely Maria Martin's case.

I have selected these few examples out of a considerable number which might be adduced, to prove the importance of a special attention to researches connected with disinterment.

* * * *

ON THE
INTERNAL ADMINISTRATION OF
PURE VERATRIA.

To the Editor of the Medical Gazette.

SIR,

THE object of the following communication is to call the attention of your numerous readers to the possibility of administering pure veratria internally, without subjecting the patient to the operation of any of those dangerous properties which all writers, and myself, amongst others, have hitherto ascribed to this substance.

The acknowledged value of colchicum autumnale in the treatment of a variety of diseases, appears to have given rise to considerable expectations that the discovery of the active principle of the plant would be of great advantage to medicine; and accordingly we find, that no sooner had MM. Pelletier and Caventon succeeded in obtaining veratria, than a number of experiments were instituted, with a view to determine its action upon the animal economy. These were principally conducted by MM. Andral and Magendie, and agree in proving it to be possessed of most energetic properties, and similar, though in a more exalted degree, to those ascribed to white hellebore, veratrum sabadilla, and colchicum, by Schabel, Orfila, Sir Everard Home, and other observers. Unfortunately, however, these properties appeared to be of such a nature as almost to preclude the possibility of veratria ever being employed

in medicine. From M. Andral's experiments on animals, it was proved that when applied directly to any of the tissues it produced rapid inflammation of the part; and that when introduced in small doses into the system, either through the medium of the veins or intestines, it occasioned violent vomiting and purging; and in larger doses, tetanus and death.

M. Magendie administered it internally in the human subject, and found that, in the dose of a quarter of a grain, it acted powerfully upon the intestines, and produced very copious dejections; and he recommends its employment on this account, as a convenient remedy in cases requiring a speedy action upon the bowels, particularly in old men, in whom he states his having used it with much advantage; he also advises its substitution for the preparations of colchicum, in the treatment of those diseases in which they had been employed. Such, however, was the dread inspired by the observed properties of the new alkaloid, that few practitioners ventured upon a trial of it; and much surprise was expressed that, with these before his eyes, M. Magendie should have ventured upon such a dangerous recommendation.

Veratria has hitherto been little employed in this country; but where it has been used, the effects produced have been nearly similar to those already recorded by practitioners on the continent; and agree with them in proving it to be possessed of great activity as a purgative and emetic: so much so, indeed, that I believe its administration has been very generally abandoned, as being fraught with greater danger, from this circumstance, than can be counterbalanced by any good effect that may arise from it. This was also my own opinion at the time my work on Veratria was published; and as the impressions I had received from the writings of others had to a certain extent been confirmed by what I had myself observed, I considered it my duty to lay them before the public. Since then, however, I have employed pure veratria internally to a considerable extent, in consequence of having observed that its salts produced none of those effects which had been ascribed to it, and in very few cases out of a great many in which it had been employed, even when given to the extent of four or six grains in twenty-four

hours, has it produced the slightest purgative effect: it has often occasioned a degree of nausea, but this may easily be obviated by taking care that too large a dose be not given at one time. To what are we to ascribe this great discrepancy in the operation of so powerful a substance? In my opinion, it may arise from one of two causes, or perhaps from both. Veratria, when first used, appears to have been obtained in part from the *colchicum autumnale*, and on this account differed in some material points from the *alealoid*, as it is now prepared from the seeds of the *veratrum sabadilla*: so much so, that it has been described as a new principle by MM. Geiger and Hesse, under the name of *colchicine*—one of the most prominent properties of which, according to those gentlemen, is to produce violent purging and then vomiting. Two counter-experiments are related by them, in one of which a small dose of *colchicine* was given to a cat; at the end of an hour it was violently purged; vomiting next came on, and then death; and upon examination it was found that violent inflammation had taken place in the stomach and intestinal canal, with sanguineous infiltration throughout their whole extent. The second experiment was made upon a younger cat, and a smaller dose of *veratria* was administered: the animal died very speedily, but neither vomiting nor purging are mentioned as having been produced; and upon examination it was observed that the superior part of the oesophagus was the only portion of the alimentary tract where inflammation had taken place; and it was remarked that this part had escaped injury in the animal which had been poisoned by the *colchicine**. These facts might of themselves be sufficient to account for the great difference in the observed action of veratria above alluded to; but it ought also to be kept in mind, that it is very probable the *alealoid*, from the large quantity which has been lately brought into the market, may now be made in a state of greater purity, from that dexterity in its manufacture which practice alone can give. Whichever explanation of the circumstance may be adopted, it certainly appears to me that pure veratria, or any of its salts, may be substituted for preparations of colchicum, not only with perfect safety, but with

considerable advantage, provided an ordinary degree of caution be observed in its exhibition.

The best form of administering it is that of pill; and the following prescription is the one I generally make use of:—

R Veratria, gr. ii.; Poly. Rad. Glycyrrh. gr. xii.; Ext. Hyosciam. gr. vi. M. fiat mass. in pilul. aequal. duodecim. divid. quarum sumat unam ter in die.

For the two last ingredients it will sometimes be found advantageous to substitute a few grains of compound rhubarb pill, especially when there is a tendency to costiveness. This prescription I have found very useful in the treatment of painful spasmodic affections, rheumatism, gout, &c. It has also been used in diarrhoea with considerable effect; and in this disease one pill ought to be given after each stool, until the relaxed state be removed. After a few doses have been taken, the patient generally experiences a sensation of warmth in the stomach, which extends over the abdomen, chest, and upper and lower extremities: this is succeeded by a feeling of tingling in various parts of the body, and frequently a degree of perspiration is induced. The same effects shew themselves when either of the salts of veratria are made use of, though perhaps in a greater degree: those which are most easily obtained are the sulphate, acetate, and tartrate; their doses are the same as that of the base itself, and a similar prescription may be employed.

I ought to apologize for trespassing upon your valuable pages; but the subject appears to me to be one of some practical importance, and this must be my excuse.—I am, sir,

Your obedient servant,
A. TURNELL.

Russell-Square, Oct. 28, 1834.

STRICTURES OF THE URETHRA, TREATED WITH THE STILETTE.

To the Editor of the Medical Gazette.

SIR,

SOME remarks relative to Mr. Stafford's urethral stilettes, which appear in the Medico-Chirurgical Review of this

* Jour. de Pharmacie, Mars 1834.

month, induce me to trouble you with another case in which, I believe, more benefit was obtained by Mr. Stafford's instrument than would have been derived from any other means with which I am acquainted.

The total absence of secrecy, and the presence of candour, which have appeared to me in all Mr. Stafford's communications, prompt me, in the first instance, to allude to the case, already published, with which my name is connected, and to state that I know of no other means by which equal advantage, with the same trifling inconvenience, could have been obtained.

The case I now allude to was one of a gentleman, about sixty years of age, who came to me with abscess in perineo, and an impassable stricture a little anterior to the membranous portion of the urethra. He had, thirty years before, suffered from stricture, and had consulted Mr., now Sir Astley, Cooper, who, he said, gave him so much pain, he had not courage again to consult a surgeon till in his present distress. A free opening was made into the abscess, which was extensive, and the larger portion of his urine passed through it, giving him intense pain. I was successful in my treatment of the stricture, and could pass a tolerable sized bougie; but though I felt satisfied, from the direction of the instrument, that it was in the prostatic portion of the urethra, I could not by any manipulation get the point of the catheter into the bladder. The patient, from continued suffering, lost his health; and, from want of appetite and sleep, was reduced almost to a skeleton. The impression conveyed to my mind from the end of the catheter produced a desire to have a controllable stilette at that point; and I requested Mr. Stafford to meet me with his instruments. The curved canula with stilette was applied, and urged on about one-third of an inch; after which a catheter of equal size was tried, but without effect. In four days, however, after the operation, the catheter passed freely, and was kept in for some time; then the patient was taught to pass it for himself, when required, but prohibited from attempting to pass urine without the catheter, till the seat of the abscess had lost all sense of tenderness, and the fistulous opening perfectly closed. Appetite, sleep, and health, were recovered, and continue,—or I am

confident I should have again been consulted.

I perfectly agree with the editors of the Review that it is not probable any one surgeon should have in his own practice twenty-one cases, in a comparatively short time, of urethral disease requiring the use of a cutting instrument; but as, with a very limited practice, I have provided Mr. S. with two cases, it is but fair to suppose that he, as the inventor of the instruments, has obtained the greater number, if not all, the cases from other surgeons. It is *not fair*, at least not kind, to imply that the cases must either have been ill treated, or that Mr. Stafford had heedlessly employed his stilette, because he had invented it. Young surgeons, who may not be so connected as to command hospital patronage, if they exert themselves, without quackery, to obtain some small portion of public confidence, should surely be treated with kindness by the periodical journals of their own profession.—I am, sir,

Your obedient servant,
W. KINGDON.

ON THE
TREATMENT OF GONORRHOÆAL
AND SYPHILITIC AFFECTIONS
WITH IODINE.

To the Editor of the Medical Gazette.

SIR,

THE facts to which the accompanying cases refer are so important, that I conceive it my duty to lay them before the public; and as there can hardly be two opinions on the subject, it would be no compliment to apologize for sending you this communication, for I do not doubt that you will consider it worthy a place in your columns.

Remaining respectfully yours,
CHARLES CASWALL.

18, Woburn Place, Russell-Square,
Oct. 28, 1834.

CASE I. — Henry Falconer, æt. 23, applied at the General Dispensary, Aldersgate-Street, on the 26th of July last, with a severe gonorrhœa, which had existed about a month; and he had been previously affected with the disease five

times. He complained of constipation, and excessive pain in emitting his urine.

He was ordered to take fifteen grains of jalap, and three of calomel, for the immediate relief of his bowels, and half an ounce of castor oil when occasion required.

The hydriodate of potash, in the form of an ointment, was also ordered (a drachm of the hydriodate to an ounce of lard), which was directed to be rubbed in along the course of the urethra twice daily, and to be applied around the penis (on lint) during the day and night.

July 31st.—The gonorrhœal discharge was much diminished, and the pain caused by the passage of the urine was not so severe. The ointment and oil to be repeated.

Aug. 2d.—The discharge was much less, and the pain had subsided. The ointment was directed to be continued.

14th.—The discharge still continued gradually to diminish. Twelve minims of the tincture of iodine were now prescribed to be taken three times a day in cold water.

Sept. 2d.—The ointment and tincture were ordered to be continued, although the discharge had entirely subsided.

On the 18th no return of the discharge had occurred, and the patient was dismissed cured.

CASE II.—George Allum was admitted a patient on the 15th of July, with gonorrhœa, an ulcer on the glans penis, and in the right groin a bubo the size of a hen's egg, in an advanced stage of suppuration. The bowels constipated.

R Pulv. Jalapæ, gr. xvij.; Hydr. Sub. gr. iij. M. Ft. Pulv. statim sumend.

R Pil. Hydr. Submur. Comp. gr. v. omni nocte manequæ.

The hydriodate of potash ointment to be applied, as in the former case, both to the urethra and the bubo.

July 17th.—The ointment and pills were repeated; a compound senna draught was ordered as an occasional aperient, and a lotion of the subacetate of lead to be applied to the ulcer on the glans.

29th.—The ulcer was healed. The ointment and draughts were recommended to be continued.

August 2d, 9th, and 14th. — The patient persisted in the use of the ointment and aperient draughts as before, and on the 19th he was dismissed cured.

CASE III.—Wm. King was admitted a patient on the 12th of August, with a gonorrhœal discharge of a week's duration, and attended with the usual symptoms.

The ointment of the hydriodate of potash was applied to the penis, as in the two preceding cases. The bowels to be relieved by castor oil when necessary.

August 16th.—The ointment was continued, and fifteen minims of the tincture of iodine were now ordered to be taken three times a day.

19th, 26th, 30th, and September 4th. —The medicines were repeated.

September 16th.—The patient was dismissed cured.

CASE IV.—Thomas Oxford, æt. 22, admitted on the 14th of August, with gonorrhœa of two days' duration.

The hydriodate of potash was used, as in the former cases, and twelve minims of the tincture of iodine were directed to be taken three times a day.

On the successive days—viz. the 16th, 19th, 26th, and 30th—the ointment and tincture were ordered to be continued.

September 4th.—The medicines were repeated.

16th.—The bowels were much confined, and the compound senna mixture was prescribed accordingly.

18th.—The gonorrhœal discharge had ceased the day preceding. One of the testicles was considerably inflamed and swollen. Eighteen leeches were therefore applied to the testicle, and a dose of jalap and calomel was directed to be taken at night, as the senna mixture had not relieved the bowels sufficiently. After the leeches had been removed, a linseed-meal poultice was applied to the testicle.

20th.—Twelve leeches were ordered, with the senna mixture and poultices.

23d.—As the inflammation had nearly subsided, and the swelling was greatly diminished, the ointment of the hydriodate of potash was ordered to be applied to the swollen testicle, and twenty minims of the tincture of iodine to be taken three times a day.

25th.—The medicines were repeated.

27th.—The patient was dismissed cured.

REMARKS.—The foregoing cases illustrate the effects of iodine in gonorrhœa, hernia humoralis, and venereal bubo. In the two latter diseases I have not used

it during the incipient stages; but I have witnessed the disappearance of a sympathetic bubo, the iodine having removed the gonorrhœal inflammation, as indeed it would be natural to expect.

The duration of the gonorrhœal discharge under this treatment is not greater, if so great, as when other remedies are employed; and the medicines in general use are of so nauseating a quality, that I conceive almost any others would be preferable. The cases I have now the pleasure of communicating sufficiently show that iodine is by no means a disagreeable substitute for cubeb pepper and copaiba. The remedy is a sure and safe one: its efficacy is perceptible from its earliest application; and under such treatment the disease continues gradually to subside, without any unfavourable occurrence.

The supervention of hernia humoralis in one of the cases to which I have alluded, was no doubt principally to be referred to the constipated state of the bowels.

It only remains for me to observe, that I have not opened a suppurative venereal bubo for the last eight months, and that I have almost invariably found the application of iodine sufficient to promote the absorption of the pus.

I cannot call to mind even a single instance in which the remedy has been unsuccessful. I have for some time past paid particular attention to the subject, and I should consider myself culpable in the extreme were I any longer to conceal such facts from the profession.

FATAL EFFECTS OF AN OVER-DOSE OF STRAMONIUM.

To the Editor of the Medical Gazette.

SIR,

IN the treatment of the following distressing case, I have to acknowledge the very kind and able assistance of my friends, Messrs. Robinson and Probert; also that of Drs. Watson and A. T. Thomson.

On Saturday, 26th ult. my little daughter, aged two years and a quarter, called, with her mother, at the house of a friend, where it appears that the child, whilst amusing herself, swallowed, unobserved, some seeds of the *datura stramonium* that were lying on a side-table

to dry for garden-use. The quantity eaten, or more properly swallowed, for there were none of them masticated, was afterwards ascertained to exceed one hundred, and weighed about sixteen grains; as ascertained by subsequently weighing a similar number of seeds.

No symptoms of a nature sufficiently alarming to arrest particular attention, presented themselves before the lapse of an hour, although, on reflection, the child had previously (indeed from within half an hour of having swallowed the seeds) evinced great irritability of temper, accompanied by general itching of the whole surface of the body, but more especially of the face; and conducted herself like a person slightly intoxicated. Her mother, ignorant of the cause of these indications, had regarded them simply as the effects of bad humour, and reproved her accordingly. To these succeeded flushed countenance, wildness of manner, suffused eyes, maniacal expression, ineffectual efforts to vomit, incoherent and rapid utterance, which very soon became wholly unintelligible; screaming, catching at imaginary objects in the air, or rather striking at them—for it was evident that these spectra were of a frightful nature, since, at the moment of darting out the hand in the direction where the eyes were fixed, she always suddenly, and with great vehemence, withdrew herself, expressed the utmost terror in her look, and then hid her face; at the same time screaming and sobbing violently. Her eye would, to appearance, follow the imaginary object for a moment or two, before she made the effort to escape from its supposed approach. She rapidly became furiously delirious, struck at, pinched, or attempted to bite, every person who came near, or any object that was offered to her.

By half-past two o'clock—*i. e.* within the space of two hours and a half from the time that she must have swallowed the poison—the child had not only lost the power of utterance, but that of voice also. She could now only utter a hoarse croaking sound, alternated with a sonorous, croupy, barking cough; and was unable to swallow, in consequence of the violent spasm which affected the muscles of deglutition*

* This symptom, conjoined with those enumerated, excited in my mind apprehensions of hydrophobia; until the matter ejected from the stomach by vomiting removed all doubt of their cause.

when she made the effort. This state of spasm, judging from the nature of the cough and the croupy character of the inspirations, pervaded also the muscles of the larynx. She now knew no person, and had been wholly insensible to surrounding objects for above an hour and a half. The pupils were dilated; had been so from the first, and continued in this state till she died. The voluntary power of the extremities was gone, and the limbs were violently agitated by spasmodic twitching and jactitation (not by regular convulsions), alternately with short paroxysms of tetanic spasm (opisthotonos).

Notwithstanding all this active excitement, accompanied with a hot and perspiring skin on the surface of the trunk, and flushed (slightly swollen) face, the pulse was almost imperceptible from the first; but, as far as it could be felt, it was natural in regard to velocity, and the inferior extremities were cold. Neither was there apparently any active determination of blood to the brain, if we may estimate this from the state of the anterior fontanelle, which was neither tense, hot, nor in the slightest degree raised by the cerebral pulsations: these, on the contrary, were scarcely perceptible.

In this condition, the severity of the symptoms undergoing occasional remissions of a few minutes' duration, she remained for about three hours, when a stage of coma supervened, but she did not sleep, though, at first, somewhat so disposed. She still continued to be affected with convulsive twitching and jactitation of the limbs, alternated with short paroxysms of rapid, vibratory, spasmodic motions, of the hands and forearms; of a peculiar, though, I believe, diagnostic nature, as regards the effects produced by poisons of this class. The muscles of the face were never affected by spasm, nor the expression of the countenance contorted in the slightest degree, during the whole course of the operation of the poison.

The comatose stage lasted about two hours: like the former, it was attended with incapability of swallowing; but evidently the cause was of a totally opposite nature to that which had produced the same symptom in the first stage. It was now decidedly the result of atony, or paralysis of those parts that had been formerly affected with spasm. A slightly stertorous state of

the breathing indicated that a similar change had taken place in the muscles of the larynx. During the continuance of the coma, the pulse returned: it was uncountably quick, and estimated to exceed 200, small, sharp, and thready; the respiration was extremely hurried, averaging about 100 in a minute: each inspiration, however, completely filled the lungs. A tympanitic state of the bowels now proclaimed itself: the belly became extremely tense, and, in consequence, prevented me detecting another symptom that manifested itself on examining the body after death, viz. paralysis of the bladder, and consequent incontinence of urine from repletion of this viscus. It need hardly be added, that the evacuations were passed unconsciously, which added to the difficulty of detecting this symptom. At one o'clock in the morning there was a return of excitement, but not so severe as that which first presented itself; neither was it attended by ocular spectra or tetanic spasm: the respiration at one time exceeded 140 in a minute. At eight o'clock on the Sunday morning she again became comparatively tranquil, and began to manifest symptoms of exhaustion, but was still affected with frequent twitching, and the vibratory motions already described. In this state she continued, gradually becoming weaker, till mid-day, when she expired, exactly twenty-four hours from the time of swallowing the seeds.

Treatment.—As soon as it was surmised that the child had swallowed something of a deleterious nature, an emetic of ipecacuanha and tartrate of antimony was administered, or rather forced down the throat; but this not appearing to be sufficiently powerful, it was followed up by one of sulphate of zinc. Such, however, was the effect of the poison on the sensibility of the stomach, that repeated doses of both these emetics were given before vomiting could be produced. The state of spasm, already alluded to, in the pharynx, likewise impeded materially a full ejection of the contents of the stomach; and, together with the age of the child, and the insoluble nature of the substance swallowed, rendered recourse to the stomach-pump inadvisable. In the course of a couple of hours, upwards of twenty seeds were dislodged; and as it was not probable that many more had been swallowed, and the efforts to vomit

were on the decline, a large dose of castor oil was forced down the throat, and an enema injected into the rectum. Both these remedies were several times repeated, and doses of calomel and jalap likewise administered, before the bowels, which appeared to be equally as torpid as the stomach, could be moved. About eight o'clock in the evening the means began to take effect, and in the course of the night upwards of eighty more seeds were discharged by stool; the child also vomited repeatedly, but brought off no more seeds from the stomach.

During the comatose state, cloths dipped in cold water were applied to the head, and ten leeches to the temples; the child was also immersed in a warm-bath. Dr. Thomson suggested that about a scruple of calcined magnesia and four drops of liquor potassæ should be given every half hour, on the presumption that it might neutralize the specific operation of the poison; but nothing appeared to have the least influence in mitigating the symptoms.

Post-mortem inspection.—The natural appearance of the body externally was not at all changed; the countenance remained placid; the limbs more supple and pliant than usual; abdomen considerably swollen, tense, and tympanitic.

The scalp, when divided, was very exsanguineous: dura mater unusually adherent; arachnoid membrane, perfectly transparent, somewhat more adherent to the pia mater than common, but not morbidly so; pia mater natural in every respect.

A medullary section of the brain might be said to present rather more red points than usual; this was observed more particularly on the left side, but not sufficiently to admit of being regarded as a morbid appearance. No effusion in the ventricles.

The blood was found to be semi-fluid throughout the body; the few coagula that were met with in the auricles of the heart and large veins were very feebly formed, and easily broken down.

The medulla oblongata was divided *very low down*, so as to afford an opportunity of judging of the condition of the spinal marrow, but nothing particular presented itself to notice.

The lungs were natural; the left ventricles of the heart were found empty; the parietes of the left side very hard,

and powerfully contracted; no coagula in the right.

A slight unusual blush pervaded the pharynx and œsophagus to about one-third their extent; but a very distinct band of vascularity, about half an inch broad, was formed at the junction of the tube with the pharynx; the larynx was similarly injected, but not quite in so marked a degree; the rima glottidis was thickened, and very turgid.

The gall-bladder was distended; bile had transuded, and was effused on the intestines. The stomach and intestines presented an extremely healthy appearance throughout; the peritoneal surface was rather paler than usual. *Not a single seed was found in the whole extent of the canal.* There was one slight invagination of the jejunum, about half an inch in extent. The bladder was distended with urine.

The only appearances, then, meriting the appellation of morbid, were those detected in the pharynx and larynx, and extending to the tubes proceeding from these.

The operation of this poison, then, it is clear, is confined principally to the nervous system. In the primary stage of excitement there may be some slight degree of increased vascular action; and in that of coma there may exist a state of congestion; but in neither condition is the degree of these respectively at all equivalent to the phenomena manifested. They are, in fact, merely secondary; a natural result of the two opposite conditions of the nervous system, to which they are referable. They should not then form the main point of treatment. Hence blood-letting, though insisted on*, should be sparingly and cautiously had recourse to. The first object, undoubtedly, is to clear the stomach and bowels of the poisonous ingesta; and the second is to neutralize, were it possible, the specific influence of the poison. The strength of the individual should be at the same time supported, as the subsequent exhaustion, resulting from the violent shock sustained by the nervous powers, is excessive.

Two cases, both children, illustrating the effects of an over-dose of this drug, are recorded in the fifth volume of the Edinburgh Medical Commentaries, by Mr. Thomas Fowler. In neither did

* *Vide* Christison's Treatise on Poisons.

fatal consequences ensue; although in one, a child six years of age, one drachm and a half of the seeds was swallowed. As Mr. Fowler states that the children picked the thorn apples themselves, it is probable that the seeds were not so matured as those swallowed by the subject of the foregoing remarks. Besides there is a material difference in the ages of the two patients, and it is not unlikely that an equal disparity in constitutional powers may also have existed. Our little patient was a very delicate child: Mr. Fowler states that his patient possessed a strong and healthy constitution.—I am, sir,

Your obedient servant,

E. W. DUFFIN, M.R.C.S.

3, Foley-Place.

MEDICAL GAZETTE.

Saturday, Nov. 8, 1834.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

NEW REGULATIONS OF THE COLLEGE OF SURGEONS.

WE last week inserted the forms of several returns required to be made to the College of Surgeons, both by teachers and pupils. Of these new regulations it is to be expected that very different views will be taken. To us the object in view, viz. that of rendering it more difficult to procure false certificates, appears to be good; but the machinery for carrying this into effect is in various respects faulty.

Of the motives which have induced the Council of the Royal College to issue the documents in question at this particular moment, we can only speak conjecturally, but we strongly suspect they had reason to anticipate that some such regulations would be recommended in the report of the Parliamentary Committee, and thus determined to take time by the fore-lock. If this be not the secret spring which moved them, they

must be looked upon as following in the wake of the Society of Apothecaries, but with the determination to outstrip them in the strictness and rigour of their “registration.”

That pupils intending to become members of the College of Surgeons should enter their names, and produce evidence of their previous education, may be very proper; at the same time we must say, that it is somewhat of the latest to issue this regulation a month after the winter courses have begun, and then to add, that “credit will be given for attendance on hospital practice, or lectures, in London, only from the date of such registry.” This would entail so great a hardship, and be so palpable an injustice, that it is obvious it cannot possibly be insisted on.

That hospital surgeons and teachers should make a return, at stated times, of those who are attending their practice or lectures, may be reasonable; but we must protest against the column for “remarks as to attendance, absence, &c.” Whatever is done, let it be done openly, but let nothing be admitted that bears the least appearance of espionage. Let pupils put down their names in the lecture-room every time they attend, or let the names even be called over, or let any more eligible mode be adopted which is open and above-board, of ascertaining the actual presence of the pupils at the lectures of their respective teachers; but let not any room exist for suspicion and distrust between them and their instructors.

The number of false certificates which we know were granted (*and we could give the names if necessary*), has rendered some regulations calculated to meet the evil almost imperative; but those which have been issued are complicated, will prove excessively troublesome, and we confidently anticipate will require to be modified.

ST. BARTHOLOMEW'S—MIDWIFERY LECTURES.

It was not our intention to have alluded to the unpleasant dispute which has occurred at St. Bartholomew's between the lecturer on Midwifery and his class; but as the same reserve has not been observed by others, we shall make a few remarks, which we hope may not be altogether useless.

In the first place, we have to state that the surmise of our contemporary, that Dr. Ashburner purchased the chair, is entirely erroneous. That a treaty was on foot with another physician, by which "a consideration" was to have been given, we are aware; but this proceeding was very properly put a stop to by the medical officers of the hospital, by whom the appointment was conferred on the present lecturer. Another insinuation against Dr. Ashburner, proceeding from the same respectable quarter, and evidently with a view of making the question a party one, is, that the gentleman above named is in some manner connected with this journal. Now both what is expressed and what is implied in this respect are utterly false, he neither having, nor ever having had, any connexion with the journal, directly or indirectly.

If it were asked why we take up this matter at all, we answer, because we think Dr. Ashburner has been somewhat harshly dealt with; and we would therefore appeal to the better feelings of his class, to let him have another trial. From Dr. Ashburner we have derived no part whatever of our information, because we should regard his representations as necessarily *ex parte*; but we have from other sources made ourselves acquainted with the facts, and have gathered what follows.

The treaty above alluded to having been set aside, the chair was conferred by the medical officers on the present oc-

cupant, who, with several others, had applied for it. Now Dr. Ashburner is regarded by competent judges as a talented and well-informed man; and it is supposed that if he had continued to lecture in the manner he had for several years done at St. Thomas's Hospital, he would have met with no opposition. Unfortunately, however, he thought himself called upon to improve his course, with a view of rendering it more worthy of his new and more numerous audience; and in doing this over-anxiously, consisted his error. We are informed that he introduced too many refinements from the German and other continental writers, with a certain quaintness, not to say pedantry, in his language, and we suppose a few little *crotchets* of his own. Now we have all known a midwifery lecturer do those very things, and yet succeed in making himself very popular, and very deservedly so: but then to effect this requires a manner corresponding to the matter—a quickness, and a self-possession, and a confidence, which Dr. Ashburner wants. Had he been less diffident, he would probably have been more successful. But it is added, that though his introductory lecture was listened to with approbation, yet that he had not proceeded half through the second one, before such opposition was manifested as appeared to result from a preconcerted cabal, and which has gone on increasing ever since. Had Dr. Ashburner now appealed to the generosity of his class to give him a fair hearing, and had he expressed an intention to recast his lectures in the simple but comprehensive mould, suited to the taste of his intelligent audience, we cannot for a moment doubt that he would have been patiently heard. Instead of this, however, the Doctor was so very ill-advised as to take up the matter in high

dudgeon, and to talk of legal measures and punishment!! Of course this speedily brought things to a climax: no set of young men could be expected to tolerate such a threat; and a regular O. P. row being contemplated, the lectures were suspended.

Under these circumstances, Dr. Loeck has very good naturedly undertaken to conduct the course *pro tempore*, and has been very favourably received. We most earnestly recommend, therefore, that Dr. Ashburner do run his pen through all his little quaint refinements (which we have no doubt he thinks the very best parts of his lectures), and that he renounce all appeal to law, or any tribunal except that of his own class; while to the gentlemen who are his pupils we say, do not suffer yourselves to become puppets, moved as Mr. Wakley chooses to pull the strings; do not let him mislead you into the idea that it is a fine manly thing to put down and inflict a serious injury upon any one—much less a member of your own profession:—the time may come when you yourselves may know what it is to ask in vain for a fair hearing and a candid auditory.

ST. GEORGE'S HOSPITAL ELECTION.

So long as the contest for the newly-created offices of Assistant-Physician and Assistant-Surgeon was pending, we avoided any reference to the subject which could affect the interests of either party. Now that it is over, we take the opportunity to express our regret that any set of men should have suffered themselves to be carried by the excitement of a canvass so very far beyond the bounds of propriety as some have been on this occasion. The tissue of falsehoods, not less malignant than absurd, which week after week appeared in the *Lancet*, and the crowning specimen of vulgar abuse which

was transmitted to the *Morning Chronicle* a few days ago, have alike contributed to disgust all candid and honourable men, and to injure, in an irreparable manner, the parties they were intended to serve. The letter from the Physicians and Surgeons of the hospital, and that of Sir Benjamin Brodie, which we subjoin, render any further allusion to the subject unnecessary.

RESULT OF THE POLL.

For Assistant Physician.

Dr. Hope 158

Dr. Dunlap..... 89

Majority 69

For Assistant Surgeon.

Mr. Cutler 178

Mr. Lane..... 98

Mr. Palmer..... 23

Majority 80

LETTER OF THE PHYSICIANS AND SURGEONS.

To the Governors of St. George's Hospital.

MY LORDS AND GENTLEMEN,—We, the undersigned Physicians and Surgeons of St. George's Hospital, beg leave very respectfully to address you on the subject of the approaching election.

We perceive with much regret that a systematic and continued effort has been made, both through the medium of the daily press, and by the verbal circulation of unfounded reports, to misrepresent the facts, and to mislead the Governors as to the considerations which led to the appointment of another Assistant-Surgeon being proposed; and as to the motives which have influenced us in the disposal of our individual votes.

With respect to the first point, we have simply to state, that on the Hospital being enlarged, it appeared to us that the welfare and comfort of the patients would be better and more efficiently attended to, if the additional duties were assigned to a responsible officer, appointed by you, than if they were met by calling in, when required, the farther assistance of dressers and other pupils, in the manner practised in those establishments where the surgical-staff bears a smaller proportion to the number of patients than it does at St. George's.

The Physicians and Surgeons of the Hospital can gain no personal advantage by increasing the number of officers: indeed, it is generally considered that the fewer the medical men that are attached to a public institution, the more may such appointments be made to serve the purposes of those who hold them. But this was not regarded by them as an adequate reason for declining to recommend an appointment which appeared to be otherwise desirable; and accordingly the question has been decided in the affirmative by large majorities (in the last instance, by more than four to one), at two of the most numerous meetings of Governors which have been convened for many years.

But dishonourable motives have been attributed to us in the selection of the candidate whom we support. In a gross and unwarrantable attack upon our colleague, Sir Benjamin Brodie, in the *Morning Chronicle* of yesterday, he is represented as having used undue influence to induce us to vote for his "private assistant," Mr. Cutler, in preference to another gentleman who is asserted to be more deserving. This allegation is absolutely untrue. With regard to the circumstance of one of the candidates having been what is called Sir Benjamin Brodie's "private assistant," the Governors must be well aware that every surgeon in extensive practice requires to have some younger surgeon to afford him occasional assistance; and that Mr. Cutler happens to be one of several who have done so, cannot, we apprehend, be fairly regarded as discreditable to him; nor can it well be urged that the experience he has thus acquired renders him less fit to be assistant-surgeon to a public institution. As to the rest, Mr. Cutler is, as a pupil, senior by several years to the other candidates; and the undersigned have promised to vote for him solely and exclusively because in their opinion the interests of the charity would be best served by his election.

The advocates of Mr. Lane, the junior of all the present Candidates, adduce as a claim in his behalf that he has established a School of Anatomy adjoining the Hospital; but it is to be kept in mind that this was a private speculation of his own, intended to bring,—and which has brought him, a profitable return. Besides, if the principle thus advocated be admitted, then would the patronage of the Hospital pass at once from the hands of the Governors into those of the proprietors of the School in question, over which no control is possessed, and which might at any time be made the object of sale and barter.

We feel assured you will do us the justice to acknowledge, that neither on this, nor any other occasion, have we endeavoured

to bias your opinion of Candidates in any unfair manner, or presumed to interfere with the absolute freedom of your choice; but the unusual circumstances which have attended the present contest, and the extraordinary and lamentable extent to which misrepresentation has been carried, have rendered it a duty to you, to our colleague, and to ourselves, to enter into the above explanation.

We have the honour to be,

My Lords and Gentlemen,

Your most obedient humble Servants,

W. F. CHAMBERS, }
EDWARD SEYMOUR, } *Physicians.*
RODERICK MACLEOD, }

ROBERT KEATE, }
CÆSAR HAWKINS, } *Surgeons.*
G. G. BABINGTON, }

St. George's Hospital,
Nov. 5, 1834.

SIR BENJAMIN BRODIE'S LETTER.

To the Editor of the *Morning Chronicle*.

14, Saville-Row, Nov. 4, 1834.

SIR,—I have seen in *The Morning Chronicle* of this day an article under the head of "St. George's Hospital," which has evidently been furnished by certain individuals who believe that, in some late transactions at that institution, their interests have not been sufficiently consulted by my colleagues and myself. As the observations there made relate especially to my conduct, and are calculated to affect my character, I feel myself called upon to request of you, as an act of justice, to lay before the public the following statement, which will, I trust, be considered as a sufficient answer to the charges which your anonymous correspondent has brought against me.

The old building of St. George's Hospital contained beds for 210 patients. The regular surgical establishment consisted of four surgeons, and of one, and afterwards of two, house-surgeons; assistant-surgeons were appointed according to circumstances; sometimes there were two, sometimes one, and sometimes none at all. For many years Mr. Keate and myself, and afterwards myself and the late Mr. Ewbank, were joint assistant-surgeons; and I must say that during the whole of that period, being daily at our posts, and anxious to be employed by any one who wanted us, we found abundance of occupation in attending to those matters to which the principal surgeons could not attend themselves. Many of the existing governors will, I am confident, bear witness to the fact that the business of the hospital was at that time well-conducted, and that no one ever found occasion to complain that the sur-

gical establishment of it was greater than it needed to be.

In the year 1828, an influential governor, on the suggestion of the surgeons, proposed that an assistant-surgeon should form a part of the permanent establishment of the hospital. It was a question whether he should propose the appointment of two assistant-surgeons, or only of one; but the surgeons recommended that the application for a second assistant-surgeon should be deferred until the building of the new hospital was completed. That time is now arrived. We have at this moment an hospital capable of containing 330 beds, and there is good reason to believe that it will not be long before the benevolence of the public will furnish the institution with the means of having the whole of it occupied with patients. Under these circumstances, the surgeons some months ago recommended to the governors the appointment of a second assistant-surgeon. The subject was discussed at two of the largest assemblies of the governors which were ever held. The arguments in favour of the appointment were then fully stated. The only arguments against it were those urged by Mr. Walker, the present assistant-surgeon, which amounted to little more than this—that at this time he had a monopoly of the office, and that the creation of another assistant-surgeon would, in some way or another, be contrary to what he supposed to be his individual interests. The result was, that at the first meeting the recommendation of the surgeons was adopted by a very large majority, and that, at the second meeting, the resolution was confirmed by a majority larger still.

The present surgical establishment of the hospital, then, consists of four principal surgeons, two assistant-surgeons, and two house-surgeons, the latter being selected from the senior and more intelligent students; and I am satisfied that the two assistant-surgeons, if they are as anxious to be employed as Mr. Keate and myself were in the early part of our career, will not fail to discover the means of being so, to the advantage both of the patients and of themselves. It is untrue that our surgical establishment is larger than that of any other hospital. At the London Hospital, which is probably of the same size as St. George's, there are three principal surgeons, three assistant surgeons, and house-surgeons also. At St. Bartholomew's Hospital, which contains 500 beds, there are three principal surgeons, three assistant-surgeons, and three house-surgeons. But those who there are designated as house-surgeons, are required to have completed their education, and must be members of the College of Surgeons; and in addition to these there is a number of

dressers, who perform the same duties, and are supposed to have the same qualifications, as our house-surgeons.

So much in answer to one part of your correspondent's statement. But he goes on to represent that I am using my influence with the governors to procure the election of Mr. Cutler, whom he describes as my private assistant, to the injury of a more deserving candidate, Mr. Lane; and I may observe, that here it is somewhat remarkable that he takes no notice of a third candidate, Mr. Palmer, a gentleman highly respected by the profession, and whose claims and qualifications are at least equal to Mr. Lane's.

Now with respect to Mr. Cutler, it is quite true that he is one of several young men, of whose assistance I have occasionally availed myself in my private practice, and that I have been led thus to employ him, on the whole, more than any one else. But it is also true that he is a much senior pupil of the hospital to any of the other candidates; and that, since he first became a pupil, with the exception of one short period, he has been engaged in a constant diligent attendance on the hospital practice. That I am not disposed to show him any improper preference is proved by this circumstance, that, in the year 1830, when there was a vacancy in the office of assistant-surgeon, I refused to give him my support as a candidate, and joined with my colleagues in supporting Mr. Walker, whose claims seemed to be at that time superior to his. But now Mr. Cutler's claims are, in the estimation of the other surgeons and myself, superior to those of his competitors; and is it to be supposed that, being satisfied, as I am, that he is the individual best qualified for the office, I am to refuse him my support, merely because I have had so high an opinion of his professional qualifications and moral integrity, as to be induced to avail myself of his assistance on various important occasions in my private practice? To say nothing of its absurdity and inconsistency, would not such conduct render me liable to the charge of having been guilty not only of gross injustice towards Mr. Cutler, but of a breach of faith with those governors who, in the affairs of the hospital, are pleased to honour me with their confidence?

I am, sir, your obedient servant,

B. C. BRODIE.

PAUPERS AND PARISH SURGEONS.

AN inquest was held this week on a poor burnt child, who was lost for want of timely medical assistance: a sad reflection, that such things can happen in this, the first city of the empire! We

do not believe that the parish surgeon was to blame in this case: in the multiplicity of his engagements he could not attend sooner than he did; but that was some hours after he could have been of any use: the patient was dead. Some observations on the present system of supplying the medical wants of the poorer classes, we are obliged to defer till next week.

CLINICAL LECTURE

ON

WOUNDED ARTERIES OF THE
FORE-ARM.

*Delivered at the Middlesex Hospital, October 25,
1831,*

BY SIR CHARLES BELL.

I BEG your attention to-day to certain cases of wounded arteries; than which there cannot be a subject more deserving your serious study: for you must perceive that the necessity of acting, and that promptly, in such cases, comes upon you most unexpectedly; that in a scene of bustle and alarm, where every one is flying to render unavailing assistance, you are required to be calm and yet decided. Now this decision, you must know well, can only be attained by previous study and much reflection—by anticipating every possible occurrence, and having learned the rule of practice. Another very important reason for attending to this subject is, that your hand, as an operating surgeon, is positively arrested until you are familiar with these cases; you can perform no great operation unless you know thoroughly well how to stop hæmorrhage and how to take up arteries. Here, allow me to say, you must err, unless you have combined the aphorism or rule of practice with a minute knowledge of the anatomy.

The education of our assistants, the house surgeon and assistant house surgeon, and I may say the surgeons in private practice in the neighbourhood of this hospital, deprive you, in a manner, of the opportunities of studying this subject; for you know, I presume, that bad surgery makes a better ground for a clinical lecture than correct practice. Distressing cases of wounded arteries do not come before you, because our young men are anatomists and diligent students, and they not only know what to do, but how and when to act. With the cases that I am now to place before you, you may contrast many that are upon record; and of these you will find an abundance in my brother's works. In that great work (which if you have not

perused, you know little of the interest which your profession is capable of exciting) you will read of the horrors which are consequent on ignorance of anatomy and of timid conduct, or of ill-advised operations; where principles have been lost sight of, or rather, we should say, never learned. When an artery has been wounded, where the surgeon has been ignorant of the anatomy—where he has, therefore, been all abroad as to what to do—where ineffectual compression has been used, and consequently the blood has been driven into the cellular membrane—a most distressing and difficult case is presented, even to the most intelligent and active surgeon: for with the ineffectual operations and pain the inflammation rises, and the cellular tissue is injected with serum, in addition to blood; so that at last, when the patient presents himself to the surgeon, there is unusual difficulty in detecting the bleeding orifice of the artery. He is not directed by the general form of the member, for it is enormously swollen, and quite changed from its natural appearance; and while he has to dissect deep, he must make his incisions through a substance with which he is scarcely acquainted, and where it is particularly difficult to ascertain the distinction of parts. Knowing this confusion of parts to present frequently to the practitioner, was the reason why, when I taught anatomy, I was particularly attentive to point out the relation of the artery to those points of bones and to the tendons, which are distinct in every condition of the limb; because, in cutting into the substance, you can ascertain, for example, the course of the extensors of the thumb, the pisiform bone, the edge of the flexor carpi ulnaris, the prominence of the point of the radius, where the general form of the arm is so changed as to afford no direction. In studying the arteries, therefore, you must be particularly careful to mark those points, which are as beacons amidst the obscurity of the parts. Having dissected the arm, you might well say, "I know where the artery runs by looking at the outward shape of the limb." But in such a condition of the parts as I have described the shape is altered, and your only directors are such points as may be ascertained in the utmost confusion of injected cellular membrane, and which will always conduct you to the course of the artery.

Another prefatory observation is, that in consequence of the aphorisms of practice being established, you have none of the difficulties to contend with that they had who have preceded you; and therefore you ought to feel grateful to those who have laboured so effectually to establish the right rule of practice.

Before proceeding to lay cases before

you, I would remind you of the anatomy and physiology of the artery. This may be best done by asking you if you are aware of what is the cause of the spontaneous stemming of blood when a vessel is opened? An artery being divided, retracts: this retraction is an important circumstance, mechanically considered, because the blood does not escape from it until the artery is stretched to its former condition; for when an artery is retracted, part of the heart's force is employed in the extension of the artery, instead of throwing the blood from it. Joined to the retraction, you will of necessity have *contraction* of the mouth of the artery. Take an opportunity, the first amputation that is performed above, of looking into the limb so amputated; put your finger upon the orifice of the divided artery (it is not necessary to place your finger on the stump of the patient, but on the surface of the amputated member), and you will find that the firmness of the artery will enable you to distinguish it blindfold; and on looking at the divided mouth, you will perceive that it is extremely small indeed. This one essential condition of an artery which has ceased to bleed spontaneously, is its retraction and contraction. But you will not arrive at a just conclusion unless, to these mechanical obstructions to the flow of blood, you take into consideration another and more important one; which arises from the life of the part. There is a relation established between the blood and the vessel conveying it: through the influence of the living vessel the blood is kept liquid, and only coagulates when that influence is withdrawn—whether by the death of the artery, by the injury to it, by pinching or twisting, or the laceration of it.

I believe I had better not pursue these prefatory remarks farther, but rather take up the cases before me and give you instances, as more likely to make an impression on your minds than any such general observations.

Sir Charles then read, from the house-surgeon's case-book, this case of

Puncture of the Radial Artery.

"Charles Bartlett, æt. 21, a shoe-maker, came to the surgery, with a wound almost exactly in the middle of the fleshy part of the fore-arm, about half an inch in length, rather towards the ulnar side of the arm, apparently not in the direction of either artery. The lips were nearly adherent, but on pressing on the sides of the cut a little clotted blood escaped; it appeared, however, of slight importance. The patient was told to go home, to poultice the wound for a night, and return the next day to have it properly dressed. However,

about eleven o'clock at night he returned, having lost four or five ounces of blood; but the hæmorrhage had been stopped by a tight bandage. We now questioned him more particularly about the history of this accident, and it appeared that he had received the wound three days ago, by a sharp-pointed knife having been thrown at him in a *lark*"—(I hope this is the patient's expression, not the taste of the narrator); "that he had lost much blood at the time, and had gone to a chemist's, who strapped it up, wound and stopped it; that on the two following days the bleeding had burst out afresh, and been stopped in a similar manner; and that the chemist now told him there was a large vessel wounded, which it would be necessary to cut down upon and tie. On undoing the bandage, a small stream of arterial blood flowed from the wound; the wound was enlarged by a longitudinal incision; the blood appeared now to come from above and below, in a more considerable stream, and seemed as if it came from the interosseal artery, yet no wound ran between the bones. Some coagulated blood was now pressed out, from a deep part of the wound next the radius. The blood then came in large quantities, and evidently from the bottom of this wound, which led in a direction towards the radial artery; it was easily stopped by pressure on this artery above and below the part wounded. The external edge of the wound being more than an inch from the artery, it was found necessary to make a regular dissection for the vessel. He was therefore put to bed, to await the visit of the surgeon next day, a compress being placed on the artery above and below the wound, which completely commanded the hæmorrhage.

"When the surgeon saw him, he would scarcely believe that it was the radial artery, and not the ulnar artery, that was wounded; the latter seemed, from the direction of the wound, so much the more likely to have been injured. The compresses were removed, but no blood flowed. He desired that the arm should be kept raised, a cold lotion applied, and that he should be sent for if the hæmorrhage returned. None appeared till four o'clock, when it again burst out. The tourniquet was put on, and the surgeon sent for. He having convinced himself that it came from the radial artery, cut directly down upon the artery, and connected his incision with the wound. The two flaps thus formed were turned back, and, after a little careful dissection, the artery was exposed, and the nature of the wound in it proved just such as was anticipated. It was punctured in such a manner as to divide one-third of the circumference, and the retraction of the elastic coat, and the

contraction of the muscular fibres, gave it exactly the appearance of having had a piece cut out. The tourniquet was now removed, and the vessel compressed above and below. The artery was divided at the puncture, and both ends tied at the distance of a few lines from the ends. The parts near the wound had been too much exposed and separated from the surrounding parts by the dissection and the injection of the cellular membrane. The wound was dressed; in five or six days both ligatures came away, and the wound soon healed by granulation."

(1.) This is a case coming the nearest of all to such as I have described, where mischief has been occasioned by imperfect compression; and I offer you the following remarks upon it:—

First, "the blood came from above and below." That to you, as anatomists, will not appear remarkable, when you recollect the free anastomoses between the radial and ulnar arteries, through the superficial and deep-seated palmar arches: but it has been imagined necessary that the anatomist should trace the anastomoses, to account for the blood returning so freely from the lower part of the artery of a limb. Not at all; in the flesh of the thigh, the shoulder, the arm, and indeed every where, there are sufficient small vessels—vessels which are exceedingly active, capable of high excitement and increased activity—to account for the flow of blood from the lower orifice; which, indeed, takes place, in certain circumstances, from all arteries, wherever divided. It has been stated in some of our books, which, in other respects, are excellent authority, that it is only necessary to take up an artery in the arm, for example, above the wounded part; but in this case you perceive that there was an immediate necessity for tying the artery above and below the wound. Even if the lower extremity does not bleed, yet, if you take up the artery only above, you are almost certain to be called to a secondary hæmorrhage; and there is such a swelling of blood from the wound, that you have difficulty in deciding whether it comes from the failure of your ligature or from the lower part of the artery, and you are under the necessity of putting down a compress most probably within the wound, thereby occasioning great inflammation, tumefaction, and a tedious cure; all of which may be avoided by taking up first one end of the artery and then the other, so that there is nothing left in the wound but thread, and no particular excitement.

(2.) My next observation is, that when an artery is punctured and does not bleed, as was the case here, it is exactly what you are to expect. You are called to a

patient who has suffered suddenly by hæmorrhage—perhaps blanched by loss of blood; you ascertain by this circumstance that a vessel has been actually wounded, but now it does not bleed. You are thrown off your guard, you go away, and you receive a second hurried message that there is another hæmorrhage. What then is to be done, when, from the circumstances of the case, the direction of the wound, the quantity of blood lost, you think the artery must have been struck, and yet the vessel does not bleed? One thing you ought always to try—and that is, to compress below the orifice, that is to say, more remote from the heart; and if the vessel have been only wounded in the side, or punctured, you will, in all probability, find that the hæmorrhage recurs—that the blood being prevented from going down the artery freely, passes out by the wound.

(3.) You must also consider whether there is any thing in the position of the limb. If a man be engaged in a struggle, and the point of the knife enters through certain muscles, the moment the arm is changed in position all these surfaces shift and lie over the wound, and the tract of the wound becomes oblique and irregular; so that a coagulum is found in the interstices of the part and around the artery. It is well sometimes to study the position of the part when wounded—to place the limb in that position by which you ascertain the tract of the wound through the several parts, and leave the passage free for the exit of the blood.

4. There is another circumstance, not to be explained on mechanical principles. An artery bleeding stops from exhaustion, and after a time the hæmorrhage again returns. I do not pretend to explain it, but such is the fact, that there is an impulse, an excited action, in the artery to resume the circulation; and sometimes this is marked by pain in the part. I have sat watching a patient, and known when to bestir myself and put my finger on the compress, from the pain striking down the limb; the pain producing an increased activity of the vessels, and that being the harbinger of a new breaking out of the hæmorrhage. Thus it seems to be a law, that a vessel having exhausted itself, shall after a time recover and resume its hæmorrhagic action. These are the circumstances that throw you off your guard, and sometimes induce you to leave a patient when he is in imminent danger of a return of hæmorrhage.

5. The next observation upon this case is very important. You will observe that the incision to find the vessel was made in connexion with the wound. That practice is quite correct, because we know very well that we have cases on record where

the surgeon has trusted entirely to his knowledge of anatomy, and has said, "I see where the artery has been wounded, I will cut down upon it;" whereas he has cut down upon the side of the vessel not wounded, and therefore has not discovered the puncture, and much unnecessary dissection, unnecessary pain, and destruction of the parts, have been the consequence. Trust to anatomy as much as you may, dissect for the artery according to your knowledge of the parts, but take the assistance of the wound itself. Either pass a probe, or your finger, through the wound, and make the incision to communicate with it; so that when the artery bleeds, it will pour the blood into the wound formed by the incision, and you will have less difficulty in ascertaining the point whence it proceeds.

6. The next observation is upon a very important and curious point: the artery appeared as if a piece were cut out. This explains why an artery does not heal. When an artery is struck, it contracts in one way, and retracts in the other; that is to say, the elasticity of the parts causes retraction, and muscular action induces contraction, so that the wound gapes; and it has no tendency to heal, because the edges are turned out. This I have seen in a way in which I could not be mistaken. When the artery of the arm has been wounded with the point of a lancet, I have seen it appear as if it were torn largely; and so the narrator states here, that it appeared "as if a portion had been cut out of the artery."

The artery was divided, and both ends taken up with a tenaculum; that is the easiest and the best way. By this means you avoid diving with the aneurismal needle, and the danger of passing it across the ulnar nerve, if it be the ulnar artery on which you are operating. If the vessel be only wounded at the side, I think the best plan is to divide it altogether, to pick up one end and tie it neatly, and then pick up the other.

The second case is that of

Division of the Ulnar Artery.

"Ellis Hayward, æt. 36, came to the hospital with a gash across the wrist, made by a piece of sheet iron falling upon it. It had bled profusely, but that had been soon stopped by winding a piece of broad tape tightly around the arm. He was faint from the sudden loss of blood, though it appeared that he had not lost much. When the bandage was removed no blood flowed, though the cut crossed the course of both arteries. The radial artery was seen distinctly pulsating in the wound, but was uninjured; the ulnar was completely divided; both ends were dis-

tinctly visible in the wound. The extremities were not involved in any clot, but were pulsating strongly, and considerably retracted, and so contracted, that not the slightest aperture was visible in their centre, nor a drop of blood flowing from them. Meanwhile a little artery of the skin was pumping away from the lower lip of the wound. The ends of the divided artery were very easily distinguished by the touch from the divided tendons and nerve. The two ends were then separately transfixed with the tenaculum, and tied, the wound dressed, and a splint and bandage put on the arm to keep the wrist slightly bent. He was sent to bed, and the arm kept wet with cold lotion. In the evening he was flushed and feverish, with a strong frequent pulse, and much headache.

"He was ordered a dose of calomel, and the Haust. Salin. c. Magnes. Sulph. ʒiiss. et Vino Ant. gtt. xxx. 4tis horis.

"Sept. 13th.—In the morning he was still very feverish, the headache severe, and pulse very strong. He was therefore bled to eight ounces, which relieved him. The bowels were opened, and the medicine continued. In the evening he became more flushed and feverish, and the medicine was ordered to be continued every two hours.

"14th.—He was much better; purged; the wound uniting by granulations; the ligatures twisted; compresses and splint reapplied. Fever again in the evening.

"15th.—In spite of care to prevent any matter being confined, a little pus can be squeezed out of the wound, and there is a slight blush around the wound; the fever, however, is less. He is a great deal reduced by purging and antimonials; no headache.

"16th.—Slept well; much better; more pus in the wound; restrictive compresses necessary above the wound, and very light dressing; only sufficient bandage to fix the splint.

"17th.—Both ligatures came away to-day, being the fifth day; both have been regularly twisted at each dressing. Half-diet and porter.

"18th.—Tendon of the flexor carpi ulnaris, and palmaris longus, sloughy.

"19th.—Made an out-patient."

1. The first point to which I would call your attention in this case, is the retracted and contracted condition of the artery, and the hæmorrhage not recurring. You will distinguish this case from the next, for here the artery was cut across by a piece of sheet-iron, which I suppose had not a very sharp edge. You will always find, that if an artery be touched with a lancet, or opened by a spicula of glass, the injury being less, it bleeds more freely than if it

be divided by a coarse instrument. In the latter case the contraction and retraction is greater, as well as the general injury to the coats of the artery; and the disposition to form coagulum is greater. You observe that the divided ends in this case were discoverable by the touch; that is just the consequence of the combination of contraction and retraction giving a degree of rigidity to the vessels, which enables you to distinguish them from the surrounding soft parts.

The third case is

Division of the Radial Artery.

"Ann Twyford, æt. 28, came to the surgery on the 6th October, with the blood dripping fast through the rags that had been hastily wrapped round a wound of the fore-arm. The wound had been received by the hand slipping off the bar of the window, in the act of pulling it down, and so thrust through the glass. It was about ten minutes after the accident that she walked into the hospital. She had lost much blood, was getting faint, and the pulse was running very rapidly. The arm was grasped above, and the bleeding stopped. The flexor carpi radialis, and the palmaris longus, and part of the superficial flexor digitorum, had been divided. The outer end of the wound terminated just over the course of the radial artery, so that it was necessary to prolong it a little to get at the vessel. The lower end of the artery was the first to bleed when the pressure was removed. After it had been secured, the upper end, which had retracted most, was picked out and tied likewise. The ligatures were slightly twisted, and the wound dressed as described in Hayward's case. She was sent to bed, and had some opening medicine.

"The 8th and 9th.—Wound dressed; looks well; ligatures twisted.

"The 10th.—One of the ligatures came away.

"The 11th.—The other ligature came away, this being the fourth day after the accident.

"The 23d.—She is still in the house, but would be better at home, as she seems to suffer from the air of the hospital, having twice had diarrhœa and a blush around the wound."

1. Connect these two circumstances together: the artery is divided by a piece of glass, and you observe the wound is bleeding all the time, and the blood is oozing through this compress of cloths. This is the character of the wound, in opposition to the last case, where the artery had been more bruised, and confirms the observation I made, that the slighter the injury to the artery, the more freely it bleeds. This

marks the distinction in regard to different kinds of wounds—lacerated, bruised, and incised. You are aware that a limb may be carried off, and no blood lost—that is, if an artery be drawn out and injured, so that a coagulum of blood is formed in it. I remember, when I first came to town, being in the society of some of the most eminent men, and the conversation turned upon this very subject. I took the opportunity of remarking, "You are considering the matter too mechanically; if an artery be torn it stops bleeding. If I amputate a breast, and the vessel spouts out, and I take hold of it with my forceps, turn it round, and twitch it, it ceases to bleed; nay, if I even take hold of it with my forceps, and squeeze it hard, the same effect is produced." "Oh, then," said my friends, "the reason is this: when an artery is torn, the inner coat being more brittle than the others, is divided into shreds, and they act as valves, so that the bleeding is stopped." That was undoubtedly an answer to my assertion, but it did not convince me; and I went down to the dissecting room, exposed the radial artery, put a strong probe under it, and tore it asunder. I then opened it, and examined it particularly, and found that although the coats had been torn, no such laceration of the inner coat as converted the shreds into valves had taken place; therefore my first position was a correct one. It is not a mechanical cause, but an effect upon the living property. You destroy the life of the vessel, or injure it to that degree, that it no longer exercises its influence in preserving the blood liquid, and it signifies not whether you twist, tear, or bruise the artery, the blood ceases to flow from it. When the principle of surgery is fairly laid down, and established in the pupil's mind, there is this happy effect, that he is not at once moved to wonder and carried away by new facts, such as this new method of twisting arteries instead of tying them.

2. Now here is the point much talked about at the present day—the torsion of arteries. There are none of my old pupils but must know what this torsion means. It does not mean that any mechanical change has taken place on the tube, whereby the blood is stopped; but that all injuries, whether from the presence of a compress, or of a ligature, or the death by gangrene, tend directly to produce this result—to cause the formation of a clot, in consequence of the relation established between the liquid condition of the blood and the healthy and natural influence of the arterial coats being destroyed.

3. One remark more on the necessity of twisting the ligatures. In several of these cases the ligatures were twisted; and observe what that means. If you take up

an artery, separate the ligature, and cut off the ends near the knot, leaving only one end, you cannot twist it, you must wait for the process of nature throwing it off. You may have observed from a late operation of cutting off the ligature from an artery, that it is not always easily performed, especially when there is only one thread.

My practice has ever been, not to cut off one end of the ligature. If the ligature be left quite free in the wound, the separate threads may be entangled among the granulations, and so retained for too long a time; but if you take the two ends, make them parallel, twist them, and lay them down, they do not interfere with the granulations, and are not entangled. On the fifth day you have an opportunity of twisting them a little more; and from the third to the fifth day they come away without the necessity of pulling upon them. The first object is not to allow the threads to be connected with the granulations; the second is to have an opportunity, on the third or fourth day, of tightening the knot without pulling; whereas, if there be but one ligature, the only means of taking it away is by pulling, and you can easily conceive what may happen.

The next case is—

Wound in the Ulnar Artery.

“Charles French, æt. 30, a coachmaker, on the 8th of October, wounded the ulnar artery with a chisel. It bled most furiously; but he immediately commanded the bleeding with the thumb of the other hand, and came running to the hospital.”

1. It is remarkable, indeed, how little pressure, if properly applied, is effectual. You see a wound bleeding, and every body hurrying to stem the hæmorrhage, putting cloth over cloth, whilst the artery seems to be working with the force of an engine; but when you expose the proper bleeding point, and press upon it with the weight of the finger, it is effectual. I could illustrate this fact with many curious instances, shewing how men very high in our profession have been mistaken in regard to the force of an artery. Into this error they have fallen from seeing the force with which the blood is splashed from an open wound, even during their compression at the groin or above the clavicle; and because they have not had occasion to notice the very slight pressure of the finger that stops the blood, when placed directly on the face or side of the bleeding vessel. (The case proceeds:—)

“When he removed his thumb the blood spouted out violently; and not being easily commanded with the hand above the wound, the tourniquet was put on. The ends of the divided artery were buried in the ragged muscle; the upper one was

picked out and tied, but there was some difficulty in recognizing it, for it had been so obliquely divided as not at all to look like an artery; the mouth being flat and expanded, instead of round and contracted.”

2. The commentary being resumed, the lecturer observed,—That is remarkable; we have just heard it stated in the former case, and I dare say accurately, that an artery divided across was retracted and contracted; but here being divided obliquely, a totally different appearance was presented. It was expanded.

“The tourniquet was now loosened, to find the lower end more easily, and blood came from it in powerful jets.”

3. So that here again you see the rule is confirmed. The upper end of the artery was tied, and the lower end began to bleed.

“This lower end was drawn out and tied, the ligatures gently twisted, the wound brought together with strapping, and a splint put on to prevent motion. On the fifth day the ligatures both came away, having been twisted at each dressing.

“Oct. 11th.—Nearly healed. An outpatient.”

4. There is one circumstance which I beg to notice, and which escaped me in its proper place. You will find in some of these cases, that it was possible to compress the artery above and below the wound; and that being done by an assistant, there was no blood in the wound. But you must not always expect to do this: if there have been bad treatment at first, the cellular membrane is injected with blood, filled with extravasated serum, and then it would be impossible, even by a tourniquet, to stop the blood, and certainly it cannot be done by compression with the hand. It is only when there is no tumefaction that the pressure of the thumb above and below decidedly and firmly can be effectual in stopping the bleeding.

Lacerated Scalp.—Abscess.—The artery opened by the lancet.

The next case is,—“A man with lacerated scalp. He had an abscess formed in the temple: this was opened with a lancet, but some bleeding followed: it was stopped, however, with a compress for a time. The bleeding returned on the two or three following days, as absorption took place below the compress. At length the wound was laid open; but the vessel could not be laid hold of by the tenaculum, but a small cut was made across the direction of the vessel; the wound remained open, but no more hæmorrhage occurred.”

Here is another circumstance in confirmation of what we learned from the other cases, that so long as a vessel is kept entangled and stretched, so long it will

bleed from time to time; but being divided, the hæmorrhage ceases. If there be bleeding from the temporal artery which you cannot arrest, divide it, and it stops. In bleeding from the temporal artery, if you cut it across you do not get enough blood for the same reason, and therefore it is your aim to open it at the side only, in correspondence with the principles shewn above.

I must once more remark, that these cases, which have been properly treated by surgeons acquainted with the anatomy of the arteries, stand in remarkable contrast with others—not only with such as are on record, but it may be with those which may hereafter come under your care; for if a wounded artery be neglected, or improperly treated in the first instance, or if the blood be confined by the closing of the outer wound without securing the bleeding vessel, a very different scene presents itself, and your difficulties are much greater than you would suppose from these narratives.

COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS IN OCTOBER 1834.

James R. Parkinson, Dublin.
H. Batson, Stanlake.
Richard Dyas, Dublin.
Charles T. Carter, Newcastle-upon-Tyne.
George Broad, Penzance.
Richard T. Smith, Manchester Street.
William Archer, Sudbury.
Joseph Hutchinson, Lincoln.
Perceval Kirton, Quebec.
Robert H. Remick, Enniskillen.
Richard T. Hunt, Wye.
Zachariah R. Stewart, Blackman Street.
Robert Palgrave, Norfolk.
George Gill, South Normanton.
William W. Webb, London.
Richard W. Martin, Chatham.
Richard Tristan, Roscommon.
James Parks, Bury, Lancashire.
George Harvey.
Charles Boyson, Newton, near Swansen.
Eagan Jones, Bristol.
Henry J. Townsend, London.
Thos. P. J. Grantham, Burgh-le-Marsh.
Gordon Gwynne, Army.
Robert James, Falmouth.
John Parker, Rochdale.
Edwin Edmonds, Penzance.
John Brownfield, Norwich.
Edward Thompson, Sheffield.
John D. Potts, London.
William Jones, Judd Street.
Roger G. C. Gardiner, Southwell, Notts.
Edwin Allen, Crewkerne.
John K. Eager, Guildford.
James Liston, Barnstable.
Samuel H. Evans, Belper.
James Hindle, Norton, Yorkshire.
Richard L. Hopkins, Army.
John C. Bellamy, Yampion, Devon.
Francis Harrison, Bombay.
John H. Watson, R.N.
Francis A. Young, Hawkhurst.
James Deane, Spalthing.
Robert Marsh, Bath.
William Jones, Henley-in-Craven.
Thomas Slipper, Lading, Norfolk.
Patrick H. Morris, Scarriff, County Clare.
Samuel C. Gardner, Burnham, Essex.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CER-

TIFICATES ON THURSDAY, NOV. 6, 1834.

Edward Hyde, Witney, Oxfordshire.
John Henry Bull, Lindfield, Sussex.
John Barker, Ixworth, Suffolk.
John Gonner Robinson, Colchester.
Jesse Leach, Rochdale.
Joseph Lancaster, Clifton.
Frederick Bell, Terington, St. John's.
Robert Kirby, Knaresborough.
Thomas Edward Rawson, Kegworth.
William Smith, Worcester.
Edward Williams, Denbigh.
Godfrey Bingley Wadsworth, Boughton, Yorksh.
Henry William Rush.
John Milligan, Bradford, Yorkshire.

M. DUPUYTREN.

THE latest account of this distinguished surgeon, given by M. Orfila in the *Académie de Médecine*, is, that there has been some improvement. M. Dupuytren had got some sleep: his respiration was better, he spoke distinctly, and the swelling was somewhat less.

CONTROVERSY BETWEEN DR. BLUNDELL AND DR. ASHWELL.

WE have perused the various documents with great pain, and must decline giving insertion to them. Dr. Ashwell's communication of the 5th has been received; but as we did not publish Dr. Blundell's second letter, he will perceive that we cannot with propriety insert his answer to it.

PERCUSSION AND AUSCULTATION

IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE VII.

DISEASES OF THE LUNGS.

CATARRH.

Symptoms—*General Signs.*—We now proceed to consider the general signs of Catarrh.

At the period when the membrane commences to swell, and even sometimes before, the patient experiences a general lassitude and inaptitude to movement; he feels cold, a chilly air seems to run in an irregular manner between his skin and muscles, and this is more particularly felt in the back and loins; the sensation is at last so complete that it produces horripilation or rigor; the skin then contracts, its papillæ become elevated, forming what is called "*chaire de poule*," or goose skin: the various functions of the body seem to have lost their energy, those of the brain evidently—perception, judgment, and reasoning—are confused; sometimes there is a singular exception to this, for those faculties become exalted for a time; the pulse is rapid but weak, the urine small in quantity and limpid. These symptoms are soon followed by irregular flushes of heat, sometimes occurring at one part of the body, sometimes at another, alternating with the cold and intermingling with it, so that the patient feels frequently, in consequence of the rapidity of these changes, the two different sensations in the

same place, and almost at the same instant; at last an universal glow pervades the frame; the pulse remains rapid, but becomes full, the urine is still small in quantity, but high coloured, the skin expands but remains dry, finally a perspiration more or less copious comes on, the functions are restored, and debility alone remains. After this febrile attack there is then a remission of symptoms, to recur usually in the evening.

The other mucous surfaces of the body frequently sympathize with the bronchial mucous membrane; thus there is often slight diarrhœa, ardor urinæ, and nocturnal seminal emissions.

CAUSES.

Individual.—We now pass on to the causes; and first to those which relate to the individual. All ages, temperaments, and both sexes, are subject to catarrh, but you usually find that persons of dark complexions, dark hair, dark eyes, or of what is called the *bilious* temperament, are most subject to the mucous form, whilst the pituitous commonly attacks those of an opposite or lymphatic habit. There are other causes relative to the individual, and to which catarrh has been attributed, but I doubt whether correctly. It has been said that the suppression of epistaxis, of hæmorrhoidal discharges, of the catamenia, and of eruptions, will produce this disease. This is a leaven of the old humoral pathology. I will not take it upon me to say that these are not occasionally causes; but I never saw a case of catarrh that could fairly be attributed to them.

There are causes which greatly predispose the individual to this affection, such as fatigue, hunger, excess of any kind, as drinking, venereal excesses, and low and humid habitations.

External.—The first and great external cause of catarrh is certainly cold, especially when combined with moisture. Cullen has exceedingly well laid down the cir-

cumstances under which cold acts. In the first place it acts upon the body in proportion to its intensity. Secondly, according to its duration: if a person be exposed to cold for a long time, he will be more liable to its effects than if he be exposed only for a short period. Thirdly, according to the direction of the air on the body: it is well known that if it be directed in a current to a particular part, its prejudicial effect will be felt sooner than if the body generally be exposed to it. The most powerful circumstances, however, in inducing disease, are the variations from cold to warmth, and from warmth to cold.

There are other causes which may be said to be chemical, and which seem to act directly by irritation, viz. the inhalation of certain gases, as of chlorine and of sulphureous acid gas. There is, however, this remarkable difference between catarrh thus induced, and that arising from cold, that the former is shorter in its duration.

Epidemic Catarrh, or Influenza.—Catarrh occasionally assumes an epidemic character, and spreads widely over various regions of the earth. It occurred in the days of Hippocrates; it has occurred also in modern times, and doubtless in the intermediate periods: there happened five instances of it in the 16th century, one in the seventeenth, nine in the eighteenth, and three in the present. This form of the disease has received a variety of names: in France it is called the *Grippe*, the *Follette*, *Barquette*, *Petite Poste*; in Italy, the *Influenza*, which latter name we have adopted.

It is impossible to form an accurate judgment from the works of old authors, as to what really was the nature of the epidemic which they called catarrhal: that the symptoms of catarrh predominated there can be no doubt, but it is extremely probable that they were combined with those of peripneumonia, or inflammation of the substance of the lungs. In the epidemic of 1782, Dr. Smith describes, besides the cough and dyspnoea, the following symptoms. It commenced with a great languor and oppression of the precordia, sighing, sickness, and great headache. The pulse was quick and irregular, and there was often nocturnal delirium; the skin was moist, with a tendency to perspire; the tongue white or yellow, muscular pains, erysipelatous efflorescence, sometimes ending in gangrene and death. The greatest danger was in the first forty-eight hours, and it attacked particularly those who were healthy and robust. As auscultation was not then known, and morbid anatomy was but little cultivated, it is impossible for us to ascertain whether the epidemic was simple catarrh, or a combination of it with pleurisy or pe-

ripneumonia; but I should think that in all probability it was the latter.

The epidemic of last year, which I cannot pass by without alluding to, occurred in two forms. In the first, it prevailed in the form of common catarrh of various degrees of intensity: the second form was evidently a combination of catarrh and peripneumonia. I did not meet with a single severe case in which there was not crepitation in the inferior lobes of the lungs; the disease was, in fact, the peripneumonia notha of old authors: the *post mortem* examinations proved it, for the bronchial tubes were filled with secretions, and the substance of the lungs was engorged with a sero-sanguinolent fluid; here and there hepatization was apparent, but the disease generally destroyed the patient before extensive consolidation of the lungs took place: in old persons the engorging fluid was less red than in the young, the affection seeming to take an intermediate character between peripneumonia and oedema pulmonum.

The general symptoms of the *Influenza* differed from ordinary catarrh in the greater degree of violence with which they commenced, the febrile symptoms being commonly of a low or asthenic type, although they occasionally put on an exquisitely sthenic form: in the severe cases, the dyspnoea became extreme, the cough troublesome, and the expectoration difficult; frequently there were violent rheumatic pains, particularly in the respiratory muscles: the local signs consisted of wheezing of all kinds, sibilating, sonorous, and mucous; and I invariably found crepitation in one or other lung, indicating effusion into the cells: congestion, more especially in the brain, soon came on, in the young, generally inducing delirium; in the old,—a muttering coma, from which they could be aroused but with difficulty. These two last signs indicated a fatal termination.

What is the cause of this disease, and of its extensive prevalence? This is a question that has occupied the attention of medical philosophers from the period of Hippocrates down to the present time, but I cannot enter here into any elaborate details upon the subject. Hippocrates attributed it to Divine agency; others have supposed it to depend upon a certain condition of the electric state of the atmosphere; and others have attributed it to terrestrial emanations, particularly Sydenham. That certain diseases are caused by miasmata arising from the earth, there can be no doubt; we have the evidence of it in intermittent and remittent fevers; but these miasmata do not act far from the situation in which they are produced, whereas influenza prevailed over hill and dale, mountain and valley, over all coun-

tries, and did not seem to depend upon local causes. Epidemic catarrh sometimes took the course of the prevailing winds; but, like the cholera of India, it frequently travelled in the very teeth of them. In this country, the epidemic appeared in weather particularly favourable to the production of ordinary catarrh; but in other places it was most violent in fine weather. That there exists a cause is certain; it probably arises from some modification of the atmosphere, but this is not yet proved. It is best therefore to avow, what all who have thought upon the subject must feel, that we are perfectly ignorant of its nature.

Another question that has arisen is, whether the disease can be propagated by contagion? We have no proofs that it can, though it was formerly supposed that it might be so extended. The following story is told by Dr. Hugh Smith regarding the epidemic of 1782:—A soldier went on a furlough to St. Alban's; the disease had not previously been felt there, but it occurred after his arrival. One instance, however, is not sufficient to prove a general rule, and I think we have no cases which decidedly shew that the influenza was contagious.

Treatment.—We must now consider the treatment of catarrh. The disease in its mild form requires very little attention; it is usually sufficient to place the patient in bed in a warm room, and give demulcents, to determine to the surface, and in a few days the disease subsides. I generally give, for the purpose of inducing perspiration, the liq. amm. acetatis, combined with small doses of Dover's powder and camphor mixture. The patient usually soon recovers his strength, and any ordinary tonic, given after the febrile symptoms have subsided, may be then administered.

But if the disease be violent, if there be much dyspnoea, much oppression at the chest, and the cough is very irritating, then it may be necessary to diminish the powers of the system by venesection, or by leeching. The quantity of blood abstracted must be proportionate to the strength of the patient, and to the intensity of the disease: it is impossible to give any other general rule. Blisters are sometimes employed, but I should recommend you not to use them during the febrile state, for they produce considerable irritation, and add to the disturbance of the individual, without being of any benefit. But when the dyspnoea or oppression continues, or if the expectoration be difficult, then they are of great advantage. Another indication is to facilitate expectoration, and for this purpose ipecacuanha is with me a very favourite remedy. It

may be given in doses of one grain every four hours. Tartar emetic has been exhibited with the same view, but I think ipecacuanha is better; it is not so liable to purge or depress. On the continent it is the custom to give emetics, and they are very useful, particularly to young children who, although they expectorate, do not spit out the secretion, but swallow it, and the result is, that the stomach becomes disordered. In adults, squills and ammoniacum are frequently of great service, but you must beware of exhibiting them to children or persons of irritable fibre, or when the disease still exists in the acute form: they are best exhibited towards the termination of the catarrh, when it tends to become chronic, and when the secreted matters are viscons, tenacious, and consequently difficult of expulsion.

One of the most teasing symptoms is cough; it commonly disturbs the patient far more than any thing else. The cough, as I have already said, is first caused by the dryness of the passages, and then by the acrid secretion. To obviate this, you may give demulcents, as oily emulsions, barley-water, linseed-tea, &c.: they seem to act mechanically, by forming an artificial mucosity, which lubricates the parts; sipping even water for a certain time will relieve the irritation, and free the patient for some hours. Sometimes the cough is so violent that the patient cannot obtain any rest, and opium then, especially after the febrile symptoms are over, is one of the most valuable remedies we possess: it acts like a charm, and gives time for a proper secretion to form.

As to the treatment of epidemic catarrh, or influenza, we have only the experience of the past year to guide us, and it was found that the moderate form required very little treatment at all; it was merely necessary to put the patient in bed, and give demulcents. In the acute, the treatment then became a matter of serious importance. Patients did not bear depletion generally, although there were exceptions to this rule, in the young and plethoric especially. Finding that there was always eripitation in the inferior lobes of the lungs, it appeared to me that mercury was one of the most proper remedies to be used, not only to subdue the inflammatory action, but to occasion absorption of the fluid effused into the air cells. I will mention one instance, strikingly illustrative of the advantageous effects of this mode of treatment. It happened to be my duty to admit the patients into this hospital, one week during the period when the epidemic was at its height: expecting a great many applications, the Committee placed at my disposal thirty-two beds, and these were all soon filled with individuals

labouring under the severe forms of influenza—so severe, that I firmly believe, if these poor people had been allowed to wander about the streets, or to remain at their own homes, with the insufficient attention they could there have obtained, they would for the most part have perished. If I recollect rightly, only one or two of these patients were bled, but they were all placed under the influence of mercury. This treatment commenced on Thursday, and by Saturday night all who were affected in the usual way by the remedy, safely and ultimately recovered, with the exception of two, and one of those had hypertrophy of the heart, with diseased aortic valves.

I should state that I never, if I could avoid it, carried on my plan to salivation, but merely rendered the mouth tender, and kept it so for a week or two. It was necessary that the action of the mercury should be prompt, and we found that the most quick and efficacious means of effecting it, was the rubbing in the linimentum hydrargyri.

The common people have a mode of treating catarrh which is occasionally successful; it frequently destroys the disease at once; but if it does not produce that effect, it will do great mischief, and perhaps destroy the patient. It is by taking wines, spices, and things of that description. The good effect of these means is produced by inducing copious perspiration; but these remedies are pregnant with high danger, if the patient be young and plethoric, and of firm fibre, or if there be dyspnoea, heat and oppression of the chest, and hard dry cough. I may here remark in passing, that there is scarcely an opinion entertained by the people at large as to the mode of treating disease, however erroneous it may be, which does not owe its origin to some old and exploded theory. This is the mode proposed by Van Helmont, but has long been disused by medical men.

Treatment of Acute Laryngitis.—The principles upon which the treatment of acute laryngitis should be founded, are similar to those of any other severe catarrh; the difference is only in the promptitude and activity with which the remedies should be administered. You will recollect, gentlemen, that the danger, and imminent indeed it is, depends upon the degree of swelling of the mucous membrane lining the rima glottidis; the more it is swollen the narrower the orifice becomes, and the smaller the column of air.

The first remedy to be used is general bleeding, and that should be carried to an extent proportionate to the intensity of the symptoms and the powers of the patient. If after bleeding, perhaps once or twice repeated, the symptoms are only slightly

diminished, then leeches or cupping may prove of service; and here I may recommend you to follow the advice given by Dr. Farre, in his excellent lectures upon this subject, which is, not to apply leeches over the external surface of the larynx, but rather along the line of the clavicles or the neck, as they often induce an œdematous state of the skin or ecchymoses, which occasion a stiffness of the parts, and add to the suffocating feelings of the patient. Blisters may also be applied upon the chest, or nape of the neck, but not over the inflamed part, and for similar reasons to those above stated; indeed, there is another reason why blisters should not be applied upon the throat, which is, that, if tracheotomy be necessary, you would then have to cut through the inflamed skin, by which the operation would be rendered more difficult.

There is no remedy of more importance and utility in this case than mercury; it is useless to employ it in small doses, for its effects must be produced rapidly—often, if possible, within a few hours: if given internally to an adult, not less than three or four grains of calomel should be administered every two hours until the mouth be rendered tender: but I do not depend upon it alone; I always direct a considerable quantity, as one or two ounces of ung. hydrargyri fortius, or the linim. hydrargyri, to be rubbed in for an hour or two, and to be repeated in three or four hours, using it without limitation until the patient is relieved. You must not be afraid of the remedy, and you will often be rewarded by seeing a permanent relief afforded as soon as the mouth is affected.

But it sometimes happens that even mercury is insufficient, or that you may be called in so late that there is no time to employ it: you perceive your patient convulsed with distress—suffocating—struggling with death—and not a moment is to be lost; then, gentlemen, the only means you possess is to establish a communication between the trachea and the air by forming an opening below the inflamed part; this is done by the operation of tracheotomy, for the description of which I refer you to your surgical works.

CHRONIC MUCOUS CATARRH.

Chronic mucous catarrh is the common infirmity of old age; it not unfrequently, however, occurs in children, particularly as a consequence of whooping cough. This disease may persist for many years.

Morbid Anatomy.—The mucous membrane is in this case usually of a pale violet colour, in patches: sometimes in old persons it has been seen very pale, or of a yellowish tint, mixed here and there with red. Dilatation of the bronchial tubes

frequently accompanies chronic mucous catarrh.

The secretion is generally of a less viscous quality than in the acute form, but more opaque; its colour is yellow, varying to grey or green; it is sometimes clouded with a dark tint, supposed to arise from a mixture of black pulmonary matter; it frequently happens that the yellow sputa are seen to float in a transparent viscous, or pituitous fluid: these sputa are commonly diffuent, but occasionally of an irregular round form; the secretion is usually inodorous, sometimes it has the smell of pus, or the discharge from a blister, or even that of gangrene of the lung: the quantity of the expectoration varies of course according to the extent of the disease; there have been thrown up as much as two or three pints in twenty four hours.

Local Signs.—The mucous rattle is one of the most common sounds heard in this disease, and to an extent proportionate to the tubes affected; the deep sonorous wheeze, and sibilation even, may be distinguished when the mucus is tenacious; but these latter sounds are not permanent, for a strong act or two of respiration, or a cough, will remove the secretions, and occasion these noises to cease: there is rarely a total suspension of the respiratory murmur, as in the acute mucous catarrh; but sometimes the necessity for respiration is so increased, that the puerile respiratory murmur may be heard nearly all over the chest. It then constitutes one of the forms of the disease we shall hereafter describe under the name of *Humid Asthma*.

Functional and General Signs.—Laennec describes, with the most perfect accuracy, the symptoms and course of this affection, in the following manner:—

“This disease is most commonly consequent upon severe acute mucous catarrh. The fever ceases without any diminution of the cough or expectoration, or changes into a slow fever hardly distinguishable, except in the evening. The patient recovers his strength and appetite, but generally remains paler and becomes thinner: in a state of repose, he breathes easily; but during exercise, with difficulty: sometimes after having lasted for many months, or even a year or two, it gradually disappears, and leaves no trace, and this occurs particularly in young persons: more commonly the expectoration and cough diminish, and even disappear in summer, although even then the patient is subject to catarrh in the dry and latent form: in winter it again becomes mucous and evident, and often its return is accompanied by fever, particularly if the expectoration be abundant: after many returns of this kind the affection remains permanent, and

in most cases, although the patient become weaker and thinner, the pulse and heat of the skin continue natural.”

I have occasionally seen so large a quantity of secretion formed as to suddenly and completely obliterate a large bronchial tube, so that the dyspnoea became instantly increased to such a degree as to threaten suffocation: in these cases relief was only obtained by a copious expectoration: this may be classed under one of the causes of humid asthma. If the secretion accumulates, and there be no power of expectoration, the disease is then called *Suffocative Catarrh*.

In some rare cases, hectic is established, the patient becomes exceedingly thin, and the disease terminates in death: indeed, so completely does chronic mucous catarrh put on then the appearance of tubercular phthisis, that none but stethoscopic means could possibly distinguish them. The following case will exemplify this fact:—

About seven or eight years since, Mr. Fuller, the surgeons' instrument-maker, living near this hospital (who permits me to use his name), was supposed to be in a state of hopeless consumption; I was requested to see him, and found he had been labouring for some months with severe cough and dyspnoea; the expectoration was puriform and copious, emaciation great, fever of a hectic character, having evening exacerbations, and terminating in night sweats, and the pulse always very rapid. The functional and general signs of tubercular phthisis were so very evident that I was hardly disposed to fatigue him by a local examination; however, upon doing so, I found no pectoriloquy, no cavernous cough or respiration, no local evidences whatever of tubercles in the usual situations, below the lines of the clavicles, but the mucous rattle was universal; here, then, was quite sufficient, in the extent of the mucous catarrh, to account for the symptoms without supposing a tubercle to exist. Leeches were frequently applied to the chest, blisters still more so, so that at one time I might say he had on an epispastic waistcoat: nauseating expectorants were given, and in a few weeks he perfectly recovered. It is in doubtful cases, like this, where auscultation is indeed of high importance.

Treatment.—There are three indications to be observed in chronic mucous catarrh:

1st. To relieve any inflammatory congestion. 2d. To free the expectoration. 3d. To give tone to the bronchial capillaries and to the general system.

First Indication.—To relieve inflammatory congestion. It frequently happens, especially during great atmospheric changes, that the acute form of mucous

catarrh will be superadded to or grafted on the chronic, and the patient's distress of breathing will considerably increase; in this case, if he be young, the abstraction of blood by leeches, or cupping, is useful; and even in old persons, if the oppression be great, I often apply a few leeches upon the sternum with advantage; general bleeding is rarely borne, I will not say that you should never have recourse to it; but you certainly should not, except the inflammatory symptoms be urgent, and the patient possess sufficient power.

Second Indication.—To free the expectoration. One of the best means of fulfilling this indication is by an emetic; it is particularly useful where the secretion is large and difficult of expulsion. The medicaments, called expectorants, are but uncertain in their operation, but we have a considerable list of them in common use; thus, ipecacuanha and tartar emetic answer best in young persons, or when an inflammatory state exists; but the aged, or those of weak, lax, and lymphatic temperaments, are most relieved by the stimulating class, as squills, ammoniacum, copaiba, tolu, turpentine, myrrh, &c.: the sulphate of zinc has been exhibited with some advantage, but I think the most powerful of all is the sulphate of copper; I am in the habit of frequently using it where the secretion is copious and viscid, and in doses of a third or half a grain dissolved in water three or four times a day.

Inhalations of tar vapour, or of chlorine, prove frequently of advantage in chronic mucous catarrhs. Blisters are of great use, particularly if the oppression or dyspnoea be considerable.

The third Indication is to give tone to the bronchial mucous membrane and to the general system. This is fulfilled, as far as relates to the membrane, by many of the expectorants already mentioned, especially those of a stimulating kind, but the direct tonics should also be combined with them, as the quinine, cascarilla, gentian, acids, &c.

One of the best tonics is passive exercise, combined with change of air, when the weather permits, as sailing and riding. I have known many instances of persons recovering from chronic catarrhs after long journeys, if these were not performed too hastily, so as to occasion fatigue.

I need not say that all the remote causes should be avoided; above all, exposure to rapid atmospheric changes; indeed, you will find it necessary to confine persons afflicted with this disease, in warm rooms during winter, for the purpose of obviating this cause.

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

IV.—On Caries.

WHAT an ulcer is in the soft parts of the frame, caries is in bone. Both of these affections are ordinarily preceded by inflammation, and are prevented when that inflammation can be arrested and subdued. Both in their progress are attended with inflammation. Both are often accompanied with partial death (gangrene in the one case, necrosis in the other) of the parts attacked. In both there is an absorption of substance, producing an excavation, commonly associated with an unwholesome and irregular growth from the ulcerated surface.

As there are different kinds of ulcers, so are there different kinds of caries: they may be divided into simple, strumous, syphilitic, and those which attend lupus and cancerous ulceration. At the same time it must be observed, that it is not always possible rigorously to distinguish each of these varieties. In some instances it is difficult to determine satisfactorily whether caries is simple or serofulous; in others, whether it is serofulous or syphilitic: so that persons well and equally conversant with disease might differ in opinion upon the nature of particular cases, who might yet admit the justness of the foregoing general distinctions.

The clearest instances of simple caries occur in the shafts of the long bones,—of syphilitic caries, in the shafts of long bones and in the cranial bones,—of strumous caries, in the flat bones, and round bones, and articular ends of the cylindrical: thus there exists in particular bones a susceptibility of particular forms of caries. For this and other reasons, I am disposed to make difference of structure in bone the basis of my arrangement in describing the varieties of caries.

I. The shafts of the long bones are liable to be affected with simple caries, syphilitic caries, and caries from cancer.

a.—The adjoined figure represents a simple caries of the fibula. At the excavated part, to borrow an expression of Mr. Syme's, the surface in the dry bone has the appearance of loaf-sugar, which has been partially dissolved by dipping into hot water. The excavation is irregular; its surface soft and porous. The

adjacent bone is enlarged from inflammation, and its cortex is likewise unusually porous, but hard.

The patient, a man past the middle age, had suffered many years with a large ulcer on the outside of the leg, which would sometimes partially heal, and then again spread to its former size. Over the fibula the ulcer was deeper than elsewhere. The appearance of the granulations was not the same at different parts of the ulcer. The portion of the surface, again, which was healthy at one time, would shortly after assume an unwholesome character, while the first became covered with florid granulations. Upon the greater part of the ulcer, the granulations were generally grey and flaccid, or greenish, or yellow and unorganized. A probe passed into the granulations covering the fibula, broke easily through a soft and gritty texture. The limb was amputated below the knee, in the Middlesex Hospital, in 1819. The tibia was found to be inflamed and enlarged. The patient died.

Simple caries is a consequence of inflammation of bone in a constitution deficient in vigour. The tibia is the most frequent seat of the disease. — It has inflamed, but instead of gradually recovering, or

forming a clean abscess, or disengaging a necrosis and undergoing a wholesome reparation, a portion of the enlarged crust softens, the cancellous structure within softens, and in place of marrow, a thick brown fluid occupies its cells. The disease is often coupled with necrosis:—a sequestrum has come away; the adjacent bone is carious. It may again be associated either with a single cavity or with irregular channels, containing pus; that is to say, with abscess. The external appearance of the limb is the same in necrosis and caries: the bone appears enlarged, and one or more sinuses open through the skin, at points where the integument is red, and soft, and sunken, and undermined.

The degree of hardness of bone varies in different instances in caries. There is in our museum a caries of the great trochanter, in which the diseased surface, though worm-eaten, is hard and solid.

Mechanical injury is a frequent cause of caries in the shafts of long bones.

The principles upon which this disease is to be treated are the following. As the disease depends upon inflammation, the remedies, general and local, which are calculated to remove inflammation of the bone, are to be employed. If these fail, as the diseased surface of an ulcer may be destroyed, so may that of a caries. But I think the removal of the diseased bone with the trephine and the chisel and the knife, preferable to its destruction by the cautery. The surgeon must bear well in mind, on this occasion, that the resources of his patient's constitution admit of being exhausted; that he may die while he is in a protracted progress of cure; and that the amputation of the limb may be sometimes preferable to the attempt to extirpate a caries.

c.—In the following figure is represented a syphilitic caries of one of the metatarsal bones. There is upon it a growth of porous bone, in two patches; the porous growth towards the lower part being riddled with irregular holes, and that towards the upper part being furrowed by longitudinal grooves. Near the head of the bone the cortex is ulcerated through, and the cancellous structure is laid bare, which had taken on the same action with the crust. In this skeleton, almost all the bones presented more or less of the same appearance.

Syphilitic caries is attended with very little enlargement. The inflammation with which it begins occupies either the periosteum alone or the periosteal surface of the bone; the periosteum thickens, and is often exquisitely painful. This renders it sometimes necessary, at an early period of the disease, to make an incision down to the bone. Occasionally, under these cir-

cumstances, a thick, viscid, glairy matter, not unlike honey, is found in cells of the periosteum. The inflamed and thickened periosteum, with more or less of porous growth of bone below it, constitutes a *node*. The cylindrical bones most frequently attacked with nodes are those which are subcutaneous—the tibia, ulna, clavicle.

In the natural progress of a node, the integuments covering it inflame and ulcerate; the skin, before breaking, has a livid colour; afterwards, the skin surrounding the ulcer has the same hue. The edges of the ulcer are commonly a little raised, and its outline irregular, and its surface is covered with unhealthy granulations and viscid ash-coloured secretion.

Syphilitic caries is often attended with partial necrosis and exfoliation.

I am not prepared to say to what extent mercury, given injudiciously, may contribute to produce syphilitic inflammation and caries of the bones; but this I know practically, that nodes frequently yield rapidly to the cautious exhibition of mercury; and that if a patient affected with nodes has not taken mercury, and is not greatly extenuated, or of a marked scrofulous diathesis, mercury alone or with sarsaparilla is the most likely remedy to succeed in at once arresting the disease. When mercury has been used with or without good effect, iodine is commonly found of striking benefit. In this capricious malady, every case is a separate study; and the skill of the practitioner is principally evinced in timing the *succession* of remedies, by which it is to be subdued.

d.—The skin is sometimes the seat of cancer. I witnessed a case in the Middlesex Hospital, in which Mr. Cartwright amputated the leg, for a cancer over the tibia. There is in our museum a tibia from a patient affected with the same disease. The tibia is deeply excavated, having suffered a passive ulceration in the progress of the cancer.

II. The flat bones are liable to every form of caries.

a.—Simple caries is not frequent in the flat bones: from their place, when it occurs in them, it is serious and intractable. I recollect an instance, under the care of Mr. Cartwright, in the Middlesex Hospital, of caries of the ilium from a pistol-shot. The patient, after lingering some months, died. In another case, which was under my care, a patient died with caries of the ascending plate of the ischium, connected with urinary fistula.

b.—Strumous caries often attacks the flat bones.

A young man, about twenty-five years of age, became my patient for caries of the bones of the head and face. A small exfoliation had taken place from the os malæ of the left side, and from the right superciliary ridge. The integuments of the right side of the forehead were swollen, puffy, and tender; there was a discharge from the nose, and a part of one turbinated bone was necrosed. No ground existed for supposing that the disease was of syphilitic origin. This patient was cured by the use of iodine, which I have found much more useful in strumous diseases of the bones than of the joints; and, when given in alternation with other tonics, than when persevered in singly for a long continuance.

A gentleman, ætat. 37, in whom the strumous diathesis is strongly marked, consulted me for caries of the palate. The incisal alveoli of the upper jaw were carious also; but this he attributed to a blow. He was liable to inflammation of the tonsils, attended with ulcers. I believe the complaint was not syphilitic. His sister, about whom I was likewise consulted, had caries and partial necrosis of the turbinated bones. Both patients recovered under treatment suited to scrofula.

The sternum is frequently the seat of strumous caries. In connexion with this complaint, matter sometimes accumulates behind the sternum in the anterior mediastinal cavity; for the liberation of which the use of the trephine may be necessary.

In giving an account of a case of spine affected with scrofulous disease, in which the vertebrae were softened and beginning to ulcerate, Sir Benjamin Brodie adds, that “the ribs were porous, their cancelli being filled with a curdy matter; they

were soft, so that they might be divided with a scalpel. Four of the ribs were separated from their attachment to the spine, and were ulcerated as far as their tubercles."

c. The cranial bones are frequently the seat of syphilitic action. The inflammation begins on the pericranial surface, but it frequently extends through the cancellous structure to the inner table. Portions of the inflamed bone often become necrosed. There is nothing in the appearance of syphilitic caries of the cranial bones to distinguish it from strumous caries. The extent of the caries (seldom considerable in scrofula), and the affections with which it is actually combined, or which have preceded it, are the only circumstances which direct our diagnosis. In dry specimens of syphilitic caries, the outer surface appears worm-eaten—perforated by ulcerated holes of different sizes; while in connexion with this, the inner table often is swollen, and porous,—prominent in irregular and broken, but smooth and shallow, edges.

A close affinity exists between the cachectic states produced by lues and scrofula. The resemblance holds not only in the features of disease, but in the remedies which are serviceable in common to both. The extreme and decided cases of the two affections are, indeed, strikingly dissimilar, but there is a neutral ground, where the two are confounded.

d. There is a form of caries which is frightfully destructive of the bones of the face. It is called *lupus*, or *noli me tangere*. It commences in the soft parts, and the bones are secondarily affected. The alar nasi is the part first attacked. The skin covering the alar nasi becomes red and hard, and ulcerates, the ulcer presenting a yellow lardaceous surface. The ulcer slowly spreads, the circumference of red and hardened skin extending with its enlargement; it gradually destroys the cartilages of the nose, the ossa nasi, the upper maxillary bones, the spongy bones, and finally attacks the frontal. The patient then perishes of inflammation of the meninges of the brain. The bone, in this disease, does not seem to be merely passively absorbed; it inflames before it ulcerates: at least, in one of two specimens in our museum, there are light ridges of porous bone formed upon the os frontis, near the boundaries of the ulceration.

The disease, when taken early, may be eradicated by the destruction of the parts attacked, with caustics. But it always has a tendency to return; nor is any medicine known to have the power of specifically correcting the latent organic vice on which it depends.

e. The lower jaw rather deserves to be

classed among the cylindrical than the flat bones: it is liable to ulcerate under two forms of cancer.

Carcinoma occasionally begins in the glandular parts at the angle of the jaw. When the ulcerative stage comes on, it involves the bone, which is absorbed to the level of the cancerous ulcer which surrounds and includes it.

f. There is another disease, which is called cancer of the lip. It is commonly produced by fretting a cracked surface of the lip. It presents the appearance of a deep ulcer in dense and indurated texture. The disease has not the malignancy of cancer. When removed by excision, it does not commonly return. This disease is sometimes allowed to make considerable progress before the patient will consent to an operation; in which case, great part of the lip may have been destroyed, and the induration may have extended to the gums and periosteum of the jaw. The bone, however, is not involved in it; so that even then, at the expense of the mutilation, the disease may be eradicated, all the soft parts attacked being removed, and the thickened periosteum entirely scraped from the bone.

III. The round bones, and the articular extremities of the cylindrical bones, are especially subject to strumous caries. The instances, even, which might admit of being considered as simple caries, most frequently occur in persons of the scrofulous diathesis.

Syphilitic caries very rarely attacks the round bones: I have seen but one instance in which this happened. The pain and tenderness with which, at one stage of lues, the joints are affected, appears to have its seat in the ligaments, not in the bones.

The round bones, again, are rarely ulcerated through cancer; not that they are less susceptible of this mode of caries than other bones, but that cancer very rarely occurs in their vicinity.

In caries of the round bones and of the articular ends of cylindrical bones, the disease derives its character and importance from the destruction with which it threatens the contiguous joints. The soft textures of the articulation are forced into disease by the irritation of the neighbouring caries. This order of the invasion of disease, is, however, of course often reversed; and caries of the articular aspects of bone secondarily produced by the extension of inflammatory action from the cartilages. The compound diseases which are thus originated, will be considered in the lectures on the pathology of joints. On the present occasion, I shall limit myself to describing such appearances in the round bones and articular

ends of the long bones, as certainly do not originate in the extension of disease from the special articular tissues; and which have been, with more or less correctness, considered either to be caries, or the state which precedes it.

1. The bones adjacent to a diseased joint are sometimes soft, so as to be readily cut with a knife, and to yield and break down under pressure; without, at the same time, any increase of vascularity existing, or change in the appearance of the medulla. This softened state of the bones is occasionally misrepresented as disease. The surgeon, after displaying the morbid alterations of the cartilages and synovial membrane of a joint, proclaims the bones diseased, because they want their usual hardness. When, however, the appearances are limited to those which I have described, the bones are not diseased: they are merely atrophied, their osseous tissue wasted;—instancing the first of the forms of atrophy which were described in the second lecture.

2. The form of caries which, in the class of bones specified, comes nearest to simple caries, is one that commences in the articular aspect of bones, and is often for a length of time—for months, I believe—confined to it; occupying, for this long period, the thickness of a line only, although eventually capable of spreading deeper into the bone.

I amputated the leg of a patient, 25 years of age, five months after a compound fracture of the tibia and fibula. The bones had shewn a disposition to unite, but the general inflammatory swelling of the limb which supervened upon the accident, never subsided. Large collections of matter formed in the calf of the leg and about the ankle. These were opened in succession, and the patient as many times rallied from the hectic fever and exhaustion which they produced. At last there formed above the knee-joint an extensive abscess, which was opened, when a profuse discharge of matter took place, and afterwards of blood and matter alternately. It was now that the limb was amputated, but too late to save the patient. In the knee and ankle-joints the cartilages were found partly absorbed, and what remained reduced to a thin shell. The articular aspect of the bone, which had become exposed, was highly inflamed. The narrowed and thin shells of cartilage which were left, were found to tear very readily from the bone: when torn off, the detached surfaces were found to be covered with bony particles, shewing that the separation must have been effected by rupturing the inflamed surface of the bone. On further examination, the whole articular aspect of the condyles was found to be highly in-

flamed and softened, for the depth of one to two lines. The bone beyond was perfectly healthy.

E. D., *ætat.* 20, was admitted in November 1833, into the Middlesex Hospital. Three years previously she had been attacked with pain and swelling of the left elbow-joint, which being treated with leeches and embrocations, went away in nine months. Shortly after her recovery the left knee began to swell at the lower and fore part; the swelling was attended with pain, which, although constant, was severe at times only: she thought it rheumatism, and wore flannel round the joint. A year before her admission the disorder in the knee became more serious; at times it confined her to her bed. The joint was hot, stiff, and painful. Several blisters were then applied in succession, and with some advantage. Leeches, fomentations, cold embrocations, bandaging, were tried, but were ineffectual. At the time of her admission, and for a month previously, she had been suffering the acutest pain, which the least pressure or motion aggravated to intensity. The knee was hardly swollen; it was a little bent. There was no impediment to further flexion but the pain it gave. The pain was severest beneath the patella; it extended through the thigh and leg. Having tried local bleeding, fomentation, a large issue, and opium, without any mitigation of her intense suffering, I amputated the limb.

Upon opening the knee joint, the capsular synovial membrane was found to be inflamed and thickened, presenting a jelly-like granulated surface, which extended a little way over the cartilages of the condyles. The cartilages were but partially ulcerated towards the joint, and for a very small extent; but they tore readily from the bones. There were parts at which it was evident they had been already discontinuous, the surface of the cartilage being slightly excavated, and the opposite surface of the bone ulcerated, and extremely vascular. At other parts the cartilage tore away with it numerous granules of bone. This arose from the surface of the bone, for the depth of a line to two lines, having been highly inflamed, and softened in its texture. Beyond the immediate surface the bone was perfectly healthy.

The preceding form of disease, commonly attended with severe pain, is, I believe, always connected with inflammation of the contiguous synovial membrane. Rest, and blisters in the vicinity of the joint kept open by irritating dressings, and issues, form the appropriate local treatment of this affection, which, when taken early, may probably be subdued.

3. The common appearances denoting scrofulous inflammation in bone, are, soft-

ness from deficiency of bone-earth, increased vascularity of the medullary membrane, and, in the place of medulla, a thick reddish-brown fluid in the cancellous structure.

In the ankle-bones of a child six years of age, examined immediately after amputation, I found the following appearances. The cartilage covering part of the posterior and upper surface of the astragalus had been absorbed; the cancellous structure below it was superficially ulcerated, and for a considerable depth was soft, as if rotten, its cells containing a thick brown fluid. The texture of the anterior part of the astragalus was healthy. When a horizontal section of the os calcis was made, about a third of its substance appeared healthy; the remaining and greater part had the brown and rotten appearance and consistence of the astragalus. The lower extremity of the tibia was in the same condition.

Sir Benjamin Brodie thus describes the appearance of the elbow-joint of a boy about ten years of age:—

“The cancellous structure of the articulating extremities of the os brachii, radius, and ulna, was so soft, that it might be crushed by a very slight degree of force, when squeezed between the fingers. It was of a dark red colour, preternaturally vascular, and there was a reddish fluid, mixed with medulla, in the cancelli.”

4. The appearance, which constitutes the most undoubted sign of strumous action, is the deposition in the cancelli of tuberculous matter—an unorganized substance, in colour yellow, and of the consistence of curd. The following instances are from Sir Benjamin Brodie's treatise on the Diseases of the Joints:—

William Miles, *ætat.* 23, underwent amputation of the leg, for disease of the knee. “On examining the knee, the articulating extremities of the tibia and fibula were found so soft that they were readily cut with a common knife; they contained much less earthy matter than is usual, and their cancelli were filled by a yellow cheesy substance.”

Charles Miller, *ætat.* 20, underwent amputation of the foot. “The extremities of the tibia and fibula, all the bones of the tarsus, and the extremities of the metatarsus, contained much less earthy matter than is usual. They were so soft that they might be cut with a scalpel without the edge being turned. They were preternaturally red and vascular, and a yellow cheesy substance was deposited in the cancelli.”

Strumous inflammation of bone is generally characterized by its insidious march, the gradualness of the local swelling, and the absence of pain which attends it. Even

when the soft textures within the contiguous joint are in process of secondary ulceration, the suffering is often comparatively trivial.

There is no reason to doubt that the disease, in its early stage, may be arrested by judicious remedies, of which the principal local means is the maintaining perfect quietude in the affected joint; and the general means, the observing those rules of diet, and medicine, and general habits, and place of residence, which tend to correct the strumous diathesis. Even when the disease has strongly established itself in a joint, there is still a remedy in amputating the limb, which is unquestionably to be resorted to if the organization of the joint is completely destroyed, and the patient's health is rapidly failing, yet no vital organ seriously affected, and strength enough left to bear the operation. To decide upon the propriety of operating in cases of less urgency, is an extremely difficult task. In some cases, where the constitutional tendency to scrofula is slight, the patient has been permanently restored to health by losing a scrofulous joint. In other cases the local disease appears to be a vent to the specific action; and when that vent no longer exists, scrofula manifests itself in other more important organs, and the patient perishes but the more rapidly.

It may happen, however, that the organs invaded (upon this hypothesis) by the returning disease may not be vital parts. Mr. Cartwright amputated a scrofulous knee in a girl seventeen years of age. Shortly after the stump had healed, several large strumous abscesses formed in different parts of the body; they broke, and the patient was reduced to great exhaustion. Nevertheless she recovered, the strumous action having fortunately fallen on the intermuscular filamentous tissue only. When the disease attacks a small joint, it is probable that the patient is in less danger of a return of strumous action on its amputation. Disease of the joint of the ball of the great toe is such an instance. In this case the place of the disease renders the patient particularly desirous to have it removed. The operation is one often performed; besides the joint, as much of the metatarsal bone being taken away as is altered in structure. I was greatly disappointed, when a gentleman, upon whom I performed this operation, after recovering perfectly, and acquiring the appearance of restored health, was in a few months attacked with symptoms of pulmonary consumption, of which he died.

It seems natural to suppose, that if there is a doubt about amputating a scrofulous joint in a patient otherwise free from disease, it would, *a fortiori*, be improper to re-

move the part, when scrofulous disease has already manifested itself in other organs. But it has been instructively pointed out by Sir Benjamin Brodie, that the removal of a scrofulous joint will sometimes palliate, or arrest, existing scrofulous disease of the viscera. He narrates a very illustrative case in these words:—

“A young woman was admitted into St. George's Hospital, labouring under a scrofulous affection of the ankle. It was of long standing, and there were several abscesses communicating with extensive surfaces of carious bone. It was evident that there was no chance of cure for the disease in the joint. Nevertheless, I did not think it right to propose to the patient that she should submit to the loss of the limb, as she had a troublesome cough, with a purulent expectoration, and other marks of pulmonary disease. She, however, earnestly implored that the ankle might be removed; and at her request, and certainly against my own judgment, I performed the operation. The stump healed readily. The pulmonary symptoms almost immediately subsided. She lived for four or five years in tolerable health; but at the end of that period (as I have been informed) there were again manifest indications of disease within the chest, of which she ultimately died.”

It is to be borne in mind, that in scrofulous affections of the joint, left to pursue their course, it is not the articular disease which is directly fatal. The patient through it, indeed, is debilitated,—exhausted with hectic fever; but that exhaustion has to produce disease in the mesentery or lungs, or in both, to prove the immediate cause of dissolution. The surgeon has then to consider whether the removal of the limb is most likely to avert the fatal visceral disease, by saving the patient from the exhaustion which promotes it,—or to accelerate its progress, by removing the vent for strumous action, which the diseased joint affords.

ON THE HYDRATED OXIDE OF IRON,

AS AN ANTIDOTE FOR ARSENIC.

To the Editor of the Medical Gazette.

SIR,

IN consequence of some experiments which have been lately instituted by MM. Bunsen and Berthold, at Göttingen, from which they concluded that they had discovered an antidote for arsenic acid, in what they term the hydro-oxide of iron, I was anxious to determine how

far the same oxide might be useful in rendering arsenious acid insoluble in the stomach. Upon reading an account of their experiments, as published in the *Lancet*, I was surprised to find that the arsenic, and not the arsenious, was the acid operated upon; because it is well known that the latter is constantly employed in this country for the purpose of destruction; and moreover, there are not more than two or three cases on record of poisoning by the former; and in these the acid was, I believe, combined with potash. The discovery of an efficient means of preventing the destructive effects of arsenious acid, has, indeed, long been a desideratum, but unfortunately, even those substances which are capable of forming insoluble compounds with this poison out of the body, such as sulphuretted hydrogen, lime &c., have by experiments, sufficiently often and carefully conducted, been found utterly useless when administered as antidotes; for even when previously combined chemically with the acid, so as to form such insoluble compounds, and introduced into the stomach, they have not been found capable of preventing the poison from manifesting its deleterious effects. But whether these effects be produced by any power which the stomach may possess of decomposing the substances introduced, and in that way setting free the arsenious acid, or whether the gastric secretions themselves be capable of exerting a solvent action on them, without any decomposition, and so allowing of their passage into the circulation, must, I fear, remain a matter of conjecture. Cases, indeed, have been recorded, in which life was apparently saved by the administration of such inert substances as charcoal, magnesia, &c., but there can be little doubt but that these acted by protecting the coats of the stomach from the action of the poison, until it could be removed from that organ. Should the following experiments therefore appear of sufficient interest, I shall feel obliged by your allowing them an early insertion.

I am, Sir,

Your obedient servant,

R. H. BRETT, M.R.C.S.

Upper Sussex Place, Kent Road.

EXPERIMENT 1.— $2\frac{1}{2}$ grains of arsenious acid, of tried purity, were administered to a rabbit of moderate size, at 20 minutes after 9 A.M. No food was

given for the first six or seven hours, during which time the animal was quite lively. At the expiration of this period, a small quantity only of food was offered, and greedily swallowed. At half-past 10 p.m. the animal appeared well, but was found dead at 8 o'clock on the following morning. Upon examination, the external jugular veins in particular, and the whole venous system, were gorged with semi-coagulated blood. Internal mouth, pharynx, and œsophagus, as also the larynx and trachea, healthy. Lungs crepitant, and floating on water. The stomach was distended with food, and almost the whole of the internal surface, particularly about the cardiac end, of a vivid red colour, with an abundant secretion of mucus of a somewhat firm consistence. The mucous membrane in several places exhibited a dotted appearance, apparently from extravasation of blood into the submucous cellular tissue. The mucous membrane readily peeled off. Rectum, and other intestines, healthy.

EXPERIMENT 2.—Rather less than 2 grains of the poison were administered to a small rabbit, and three or four minutes afterwards 8 or 10 grains of the hydrated oxide of iron. This animal died in less than three hours, remaining throughout in a torpid state, but not apparently suffering from pain. Upon examination after death, the heart and venous system gorged with fluid blood; lungs healthy, as were also the œsophagus and trachea; stomach distended with food. There was a considerable quantity of mucus covering the lining membrane, which last exhibited no signs of inflammation. The rectum and intestines generally free from inflammation. It may be observed, that a small quantity of water was introduced into the stomach of this rabbit after the administration of the acid, and oxide of iron.

EXPERIMENT 3.—A portion of arsenite of iron was prepared by precipitation from the persulphate of iron by means of arsenite of potass. The precipitate, after being washed for some time with boiling water, was dried by a gentle heat. 5 grains were administered to a full grown rabbit, at 10 a.m. The animal appeared little or not at all indisposed until 6 p.m. when it became inactive and refused food. It continued in this state for two hours, when it made violent muscular exertions, and was evidently gasping for breath,—while it occasion-

ally uttered a loud tracheal rattle. In a very short time it died. This animal could not be examined till some hours after death, when the pharynx and œsophagus were found healthy; larynx and trachea, as far as the bifurcation of the latter, much inflamed: the lining membrane was covered with a considerable quantity of mucus. Right lung morbidly red, and less crepitant than natural; venous system gorged with coagulated blood; stomach full of food; mucous membrane covered with a layer of mucus of so solid a character as to adhere and peel off in part with the contents of the stomach. This last was much inflamed, especially about the cardiac end, at which part some extravasation of blood had taken place beneath the mucous membrane. Rectum, and lower part of large intestines, healthy.

EXPERIMENT IV.—Six grains of arsenite of iron, mixed with about the same quantity of free oxide, were given to a full-grown rabbit; but as this was administered late in the evening, the symptoms and length of time taken to produce death could not be conveniently estimated: the animal was found dead early on the following morning. Upon examination, the venous system was found gorged with coagulated blood; air-passages and lungs healthy, as was also the œsophagus; stomach distended with food, and lined with mucus of the same character as in the last experiment. The cardiac end of the stomach was much inflamed; there were also patches of extravasated blood; intestines quite healthy.

The first experiment was made for the purpose of marking the morbid appearances produced by, and length of time necessary for, a certain dose of the poison to produce its effects.

An objection may, perhaps, be made to the second experiment, and it may be urged that had the antidote been administered in larger quantity, death would not have ensued. It is sufficient at present to observe, in reply, that the quantity of oxide of iron was more than sufficient to neutralize the arsenious acid, had chemical union taken place.

In the third experiment, the poison and antidote were given chemically combined, but still the animal died; as did also that in Experiment IV. where free oxide of iron was mixed with the arsenite of iron.

It now became an object of inquiry, Will arsenious acid and the hydrated oxide of iron combine, when suspended together in water, the temperature being favourable? What was the nature of the precipitate produced by the addition of arsenite of potass to the per-sulphate of iron, both before and after it had been well washed with boiling water, in which last state it was administered to the rabbits in Experiments III. and IV.?

A.—One grain of arsenious acid was dissolved in one ounce of boiling water, and the solution allowed to become cold. No crystals were deposited. Eight or ten grains of oxide of iron were then suspended through the solution, and the whole kept at a temperature of from 95° to 100° for nine hours; the fluid was agitated from time to time. The whole was then thrown upon a filter, and the filtered fluid found to contain an abundance of arsenious acid, as indicated by liquid re-agents.

B.—The same quantity of arsenious acid was boiled with eight grains of the oxide of iron in water, for half an hour. The filtered fluid gave equally abundant indications of the presence of the poison; the residue on the filter was washed with boiling distilled water, so long as the filtered fluid gave any indications of the presence of arsenious acid; the filter and its contents were then dried at a gentle heat: the residue, which was of the colour of oxide of iron, gave slight indications of the presence of arsenic when heated with charcoal.

C.—An excess of arsenite of potass in solution was added to a persulphate of iron; a fine canary-yellow coloured precipitate came down, soluble in the acids and in ammonia.

D.—A solution of arsenious acid was added to a per-sulphate of iron: no precipitate ensued.

E.—A solution of per-sulphate of iron was added in excess to one of arsenite of potass: the yellow precipitate obtained was collected on a filter and washed with cold distilled water; after some time the filtered fluid ceased to give indications of arsenious acid; the precipitate retained its yellow colour.

D.—A portion of the same precipitate was then washed repeatedly with boiling distilled water, and it was only after some hours that the filtered fluid ceased to give indications of arsenious acid;

it gave no indications, however, of the presence of iron; the yellow colour was supplied by a brick-red one, similar to that of the oxide of iron; the precipitate was dried by a gentle heat; when heated with charcoal it gave proofs of the existence of arsenic.

From experiment A, it would appear that even excess of per-oxide of iron will not neutralize arsenious acid, even when this last is in solution, and the time allowed very considerable. It is clear, therefore, that no beneficial results can accrue from the administration of this substance as an antidote, in cases of poisoning by arsenious acid; for in such cases the neutralization of the poison ought to be immediate, and the circumstances are also exceedingly unfavourable for the action of the acid on the metallic oxide: even admitting that a small portion of these substances do unite chemically at such a temperature, the excess of uncombined arsenious acid would not fail to cause death.

In experiment B, the circumstances were still more favourable for the entire neutralization of the poison, the temperature being so high; but in that case, the yellow arsenite noticed in experiment E could not be formed, in consequence of its undergoing decomposition at a boiling heat, yielding up its arsenious acid; but still it might have been expected, that as sufficient oxide of iron was present, the whole of the arsenious acid would have combined with it, constituting the brown arsenite noticed in experiment D.

E.—In this experiment the yellow arsenite was formed, and found to retain its colour when washed with cold distilled water; to which fluid it does not yield up its arsenious acid: boiling water, on the contrary, decomposes the salt; depriving it of a very considerable quantity of its arsenious acid, and altering its colour. I am inclined to consider the yellow and the brown as two distinct arsenites, the arsenious acid in the former being in much greater proportion than in the latter. That the arsenious acid in the former is not in a state of mere mechanical mixture with the oxide of iron, is shewn by the colour of the compound; one of the strongest proofs of chemical union.

I have not had time to examine the proportions in which the acid and oxide unite in these two arsenites; but supposing, in the first case, that the salt

consists of two atoms of acid to one of base, the combining proportions would be 100 acid to 40 oxide. Still there would have been more than sufficient oxide of iron, both in the experiments on the rabbits as well as in those last detailed, to have combined with the arsenious acid employed; and the same may be said of the second arsenite, in which the proportion of arsenious acid is much smaller; for supposing that there were two atoms of base to one of acid, the proportions would be 50 acid to 80 base: the quantity of oxide of iron, therefore, employed in the experiments alluded to, was more than sufficient to allow of such a combination, and the consequent neutralization of the whole of the arsenious acid present.

From these experiments, I conclude that the hydrated oxide of iron cannot be administered as an antidote for arsenious acid with any chance of success, and that, like other reputed antidotes, it most probably acts by protecting the coats of the stomach from the action of the poison, and not by rendering the poison insoluble. From a few experiments performed on arsenic acid, I am inclined to believe that the same objections may be advanced as in the above instance; but further investigation is required to clear up that point.

REPORT OF

CASES IN WHICH ERGOT OF RYE WAS USED*;

With its Effects.

By FLEETWOOD CHURCHILL, M.D.

Physician to the Wellesley Female Institution,
Lecturer on Midwifery, &c.

THE various opinions which have latterly been put forward as to the utility of the ergot of rye—its use in various diseases—the doses in which it should be given—with the good and evil effects produced by it—have induced me to throw together a few of the cases in which I have tried it, and of which I took accurate notes at the time. In many of these, and in some of those related by others, an important oversight has, I think, been committed, in not ob-

serving the pulse *immediately* after each dose. In two cases which I shall relate, we may observe that the primary effect of the ergot occurred very shortly after its administration, and was followed rapidly by another and very different state, which has usually been considered as its direct effect. All medicines of great power are liable to produce ill consequences sometimes, in connexion with the good derived from them,—sometimes as their sole effects: thus it is with ergot. We meet with cases where life is apparently preserved by it, without a single unfavourable symptom occurring; in others (as in Cases I. II. and III.) the object for which the remedy was given is attained, but distressing circumstances accompany it; whilst in a third class no good is done, and the evil alone is prominent.

CASE I*.—Mary R., in her fourth month of pregnancy, was seized with hæmorrhage after fright. During this first attack, I was afterwards informed, she aborted. For some days I tried the ordinary remedies,—opium, an acid mixture, cold to the vulva, and plugging,—without success. After a short interval the flooding returned, expelled the plug, and reduced the patient to a state of anemia. Nothing peculiar was discovered by examination *per vaginam*. As no time was to be lost, I then gave her \mathfrak{ssj} . of the ergot in three doses, with intervals of an hour. The stomach retained the whole. No pain was felt in the belly for some hours, when she said she felt a slight sting. *The hæmorrhage stopped entirely*. The next day she complained of violent pain in the head, and became delirious for some hours. These symptoms were relieved by purgatives, shaving and blistering the head, &c., and she gradually recovered so as to sit up and walk about her room. In about a week, after some greater exertion than usual, she had a recurrence of the flooding. The ergot again relieved her, after opium and cold to the vulva failed; but it was followed by similar excitement, though in a much slighter degree.

CASE II.—Mrs. F., two months pregnant, was attacked with hæmorrhage,

* An abstract of my notes on this case was given by my friend and colleague, Dr. Maunsell, in a report of the Wellesley Institution, published in the Dublin Journal for July 1834. They were then introduced merely to shew the occasional bad effects of this remedy.

* Read at a meeting of the Association of Physicians, Dublin, Oct. 6, 1834.

for which the usual means were employed. The next day (April 22, 1834) I saw her, as the discharge had recurred in an alarming degree; and I ordered ʒss. of ergot in two doses, with an interval of fifteen minutes between each. After sleeping awhile the discharge returned, and another dose (ʒj.) was given with perfect success. She aborted, and *no hæmorrhage followed*. On the next day she was in a state of half-stupor, with violent headache, and weak, quick, depressed pulse. These symptoms yielded to appropriate remedies, and she recovered.

CASE III.—Mrs. —, in Leeson-Lane, after being safely delivered of a living child, on the expulsion of the placenta was attacked with violent hæmorrhage, for which the pupil in attendance applied cold to the vulva. When I arrived, I found her blanched, with very feeble pulse, and complaining of great faintness. I gave her ʒss. of the ergot, in two doses, with an interval of half an hour, and no stimulants. *The flooding entirely ceased*. On visiting her a few hours afterwards, I found her rather feverish; skin hot; pulse very rapid; and a very slight headache. These symptoms subsided without remedies, and she got well.

CASE IV.—Mrs. —, Stephen-Street, three months pregnant, was seized with flooding, and the fœtus was expelled, but no secundines; and I was called in. Cold had been applied to the vulva without effect, and she was much reduced by the bleeding. On examination *per vaginam*, I could distinctly feel the membranes within the os uteri, but could not extract them without introducing my hand, which I deemed inadvisable. One drachm of ergot was given in three doses, with half an hour's interval between each; and the pulse was carefully noted every few minutes. Five minutes after the first dose it had diminished six beats in frequency, and was weaker. From this point it gradually rose to its former standard; and this was exactly repeated with each dose. No excitement followed, and the patient perfectly recovered.

CASE V. was a patient, Mrs. M., aged 45, in lingering labour of her first child. The parts were of proper size, but the uterine contractions decreased in force and number. After a considerable time

had elapsed, and other means had been tried, ʒj. of ergot was given in ʒj. doses, at half-hour intervals. The pulse, which beat 96 when the first dose was given, in five minutes fell to 69, and then gradually rose up to its standard at first; and this occurred with each dose. The pains were increased in frequency, but not in force, and the forceps was finally employed. There remained a sort of stupor over her after the ergot was given; but whether caused by that, or by the duration of labour, may be difficult to decide.

CASE VI.—Mrs. — aborted a fortnight before I saw her, and since that time had continued to suffer from a profuse sanguineous discharge, which reduced her considerably. I prescribed gr. v. of the ergot to be taken three times a day; and after taking four or five doses the flooding diminished, and soon ceased altogether. No bad symptom followed.

By way of illustrating the unmitigated ill effects of this remedy, I may refer to a case communicated to Dr. Maunsell by Dr. Johnson, related in the same number of the Dublin Journal, in which a double dose was given by mistake to a person in labour. No uterine contractions were produced, but the patient was attacked with "incomplete coma, livid face, and muttering delirium," which continued thirty hours.

From the cases I have related, may we not conclude, that the primary action of ergot of rye is sedative (Cases IV. and V.), followed quickly by more or less excitement, in some cases by delirium. How long this state would last, and whether it would subside spontaneously, we cannot say positively. In one patient (Case III.), where remedies seemed unnecessary, it did so subside; but in the others it would have been unjustifiable to have neglected the means in our power, and which were speedily successful.

I know not of any cases in which these symptoms proved very obstinate. The inference, therefore, that I would draw from these trials is, that as ill consequences do result from its use, it requires great care in the administration of it; but that its positive value is but little diminished, and its exhibition not interdicted by this circumstance; for we see that in two cases it probably saved the patients' lives, even where

it occasioned the appearance of head symptoms. In another case it rendered unnecessary the manual extraction of the secundines at an early period; and in a third it controlled a very obstinate menorrhagia. I fear that at present our knowledge of its effects on different constitutions is too limited to enable us to distinguish beforehand those cases in which ill effects may be anticipated. We ought certainly to abstain from its use in any case where there is cerebral excitement.

It is very desirable, whenever ergot is given, that an accurate estimate of the pulse at the time of administering it should be taken, and that notes of its frequency should be made every five minutes afterwards. I am unable to explain why the same doses should act so powerfully in one case, and not in another; for in the trials I made it was as fresh, and apparently as good, when given to one patient, and when ordered for the others. The mode of exhibition I adopted, was to boil the bruised ergot in a little water for a few minutes, then adding a little milk, to give both the decoction and the ergot. The addition of the milk renders it more palatable, and less likely to provoke vomiting. We should be careful, however, to increase the bulk of the medicine as little as possible, as that alone would irritate the stomach.

It will be observed that I always gave it (with one exception) in scruple doses; and I do not know whether, in cases of such imminent danger, we should be justified in giving smaller doses, as much more time would be required before the full effect would be obtained.

MODIFICATION PRODUCED ON CASTOR OIL,

IN PASSING THROUGH THE BOWELS.

To the Editor of the Medical Gazette.
SIR,

I SHALL feel obliged by your publishing the following remarks on the curious modification which castor-oil is capable of undergoing in the intestines. The experiments were performed for the purpose of determining a chemical distinction between the fatty masses occasionally found in the alvine discharges (a

circumstance rendered highly interesting to the profession generally, since the publication of Dr. Bright's opinions on that subject), and the different forms which castor-oil is known to assume when mixed up with fecal matter. It is well known that when the oil has been administered, either by the mouth or as an enema, it may be traced in the dejections under several modifications; sometimes resembling caseous flakes, or a soap-like scum, floating on the more fluid part of the dejection; occasionally it has been seen arranged in a form not unlike bunches of grapes, or more nearly of hydatids of a whitish colour: more generally, however, it is found mixed up with the feces as a kind of emulsion, and in some few instances (of which the following case is an example) it has been discharged under the form of solid tallow-like masses.

A woman, about eight months advanced in pregnancy, was admitted, a few weeks since, into Martha's Ward, (under Dr. Bright) labouring under constipation, frequent vomiting, and a burning sensation at the scrobiculus cordis. Some medicines were prescribed for her, and an enema of castor-oil was ordered to be injected. This was done; the injection did not return until the following day; it was mixed with feculent matter, and contained also a portion of the castor-oil: besides this, some solid tallow-like masses were found on its surface; these were given to me for examination, by Dr. Bright. The woman has never since passed a similar substance, and she is now convalescent.

Examination of the Fatty Matter.

1. It is a white soft substance, of a fetid penetrating odour, sinking in water, insoluble in that fluid, although it causes it to form an imperfect lather when rubbed between the fingers; without any appreciable action on either litmus or turmeric paper.

2. Exposed to heat in a bent glass tube, it partly fuses, swells up, gives off water, and at a temperature just below that at which it changes colour, a little ammonia is evolved; and on increasing the heat, the semi-fused mass exhales a powerful odour of boiling "soap-suds," or "lees."

3. When boiled in alcohol of 830, the fatty substance almost entirely disappears, and a solution is obtained,

which appears turbid, in consequence of numerous very minute flakes being in suspension; on cooling, the fatty matter is deposited as a light spongy mass (two or three times larger than the bulk of fat employed); this was redissolved in alcohol, filtered while hot, and, on cooling, numerous fine needles of stearine were deposited.

4. Another portion of the fat was placed in boiling liquid potass: it swelled, become amber-coloured, translucent at the edges, and eventually dissolved. By cooling, a white solid soap was obtained, soluble in water and alcohol, which afforded fine pearly flakes on the addition of an acid.

5. An alcoholic solution of the fatty matter was mixed with nitric acid, and set aside. In a few hours the surface of the fluid became covered with floating laminae, of a yellowish colour and pearly lustre, bearing, at first sight, no inconsiderable resemblance to nitrate of urea. This crystalline matter, however, readily fused into yellowish oily globules.

6. Another portion of the fatty matter was boiled for some hours in water, acidulated with acetic acid; when cold, the whole was thrown on a filter, and well washed with distilled water. The fat had now assumed a yellowish tint, and lost the property it before possessed of forming a soap-like lather with water; it had also become perfectly fusible, at a temperature of 145° , appearing then under the form of a yellowish oil, of a peculiar rancid odour.

7. On submitting the fat (obtained in experiment 6, by boiling the original matter with an acid) to distillation, an oil was obtained in the receiver, which, when cold, became a striated crystalline mass, possessing an acid reaction and pungent odour; to this substance some recently-prepared protoxide of lead was added, and the mixture exposed to a temperature of 160° : a mass was obtained, soluble in cold alcohol; the alcoholic solution exerting an *alkaline* reaction on litmus paper, previously reddened by an acid, and affording a copious precipitate of lead on the addition of liquid sulphuretted hydrogen.

From all these experiments, but chiefly from the reactions described in experiment 7 (which are quite peculiar to castor oil), I have scarcely a doubt that the fatty masses under examination were merely the oil which had under-

gone some change in the intestines; this change, I am inclined to believe, consists in a process of saponification: a portion of the oil, by combining with alkaline matter, as well as a little albumen, forming a solid soap, which is combined with uncharged oil in a state of minute admixture. I feel more certain of this fact, as I have since been able to form an artificial compound, much resembling the fatty masses. Both soda and ammonia, although in comparatively minute quantities, appear to be present in the fatty matter.

The following are the results of a quantitative examination of this matter.

Stearin and olein	39.00
Water, with traces of ammonia	7.80
Albumen	0.50
Soda	1.15
	<hr/>
	49.45
Loss	1.55
	<hr/>
	50.

I am, sir,
Your obedient servant,
GOLDING BIRD.

Guy's Hospital, Nov. 8, 1834.

IMPERFORATE ANUS SUCCESSFULLY TREATED.

To the Editor of the Medical Gazette

SIR,

SHOULD you deem the accompanying case of imperforate anus of sufficient interest to occupy a column of your journal, I shall be obliged by its insertion at your convenience.

I am, sir,
Your obedient servant,
ROBERT DYCE, M.D.
Assistant Staff-Surgeon.

Maidstone Barracks,
Nov. 3, 1834.

On the 5th of October last, I delivered a woman of a female child; the first of seven children born alive. The labour was natural. The following day a dose of castor-oil was given to the infant, which, not operating, was repeated at 3 p.m. the same afternoon. At my evening visit I found there had been neither water nor motion passed, which

led me to examine the anus. I found its form externally was tolerably perfect,—however, with rather a more ragged appearance than usual; but on introducing a bougie, it was stopped in its progress about an inch and a half from the external aperture. My finger, when beyond the sphincter, conveyed the sensation as of entering a vacant space, into which projected a small tumor. After some consideration, I introduced the canula of a trocar up to what appeared to be the impediment, and pushed the stilette on to its utmost extent; but no meconium followed. A medical friend of mine, who was kind enough to visit the child along with me, tried the same means, as also the introduction of a grooved needle, but with no better success. Our efforts also to hit upon the urethra were equally unsuccessful. It was then determined to wait the result of a greater distention of the gut, as no urgent symptoms had as yet shewn themselves. On Tuesday (second day) the child was reported to have had an uneasy night, to have vomited repeatedly, and latterly to have refused the breast. The abdomen was very tense and swollen, and the labia enlarged and livid. Nothing had passed either from the rectum or bladder. Another attempt was then made: I introduced my finger into the anus; the impediment was felt more distinct and prominent; a pharyngotomos was then passed flatly along the finger as far as the obstruction, and the lancet pushed firmly on. In a few seconds I had the satisfaction of seeing the meconium pass freely by the finger. A very slight hæmorrhage followed. A hot-water injection was thrown up, which brought off a considerable quantity of hardened meconium, with evident relief to the child.

Still no water had been passed; and every attempt, on this as on the former occasions, to find the urethra by a probe, was unsuccessful. A warm-bath was directed, and fomentations to the abdomen to be repeatedly used. A few hours after, the child was said to have had three blood motions, to have had no vomiting, and there was rather less tension of abdomen. At this time our attempts were renewed to open the natural passage to the urethra and bladder, and we were deliberating what had better be done in case of failure, when happily,

on using some force by pressure with the probe, the resistance was overcome, and urine flowed freely. A dose of oil was now given, and the fomentations directed to be continued.

Wednesday (third day).—The abdomen was found still tense, though less so, and with some œdema of the lower part. The labia were less swelled and livid. The child had been easy, sucked well, and had three or four motions, less bloody and more feculent, but no water. A probe was again introduced, and easily entered the urethra. At this time a tea-cupful of high-coloured urine came off. For eight days from this period, the occasional use of castor-oil was all that was required; conceiving that free action of the bowels would keep the orifice in the rectum open, and obviate the necessity of using bougies. In this I was mistaken. The wound was evidently at this time contracting; the stools were thin, and in small quantity; a good sized bougie was therefore introduced twice a day for ten days, when, both functions being performed regularly, I desisted. The child has now, I consider, been well for the last week.

A similar case to this has been mentioned to me, as occurring in the practice of a civil practitioner within the last few days, where the trocar was also unsuccessfully used.

If a single instance in my own hands, and the report of a second case in those of another, would justify my hazarding an opinion, I would say, that, of the two instruments, the trocar and pharyngotomos, the latter is decidedly the preferable. From the elasticity and little resistance offered by the gut, and the trocar not having so keen an edge, it will be more likely, instead of entering, to push the gut before it, as must have happened to myself; whereas the pharyngotomos will penetrate freely, like a lancet, and has, besides, the advantage of enabling the operator to enlarge the wound by a crucial incision, by simply turning the flat surface of the instrument from off the finger, and introducing it at right angles.

ON THE SPINAL NERVES OF THE
TURTLE.

VALUE OF COMPARATIVE ANATOMY.

To the Editor of the Medical Gazette.

SIR,

IN the turtle, the anterior bundles of the cervical nerves are much larger than the posterior. Throughout the shell, nearly as far as the sacrum, the anterior bundles are only just discernible with a magnifying glass; the posterior appear, therefore, to form the principal part of each nerve. The anterior bundles of the sacral nerves, or those supplying the lower extremities, rectum, &c. are somewhat larger than the posterior. It is hardly necessary to remark, that in the neck and anterior extremities there are very large muscles, but very little integument. The principal portion of the dorsal nerves enters into the structure of the large shell, and these, therefore, require only a few filaments from the anterior surface of the spinal cord. The nerves given to the lower extremities have to supply a larger proportion of integument than muscle, as compared with those of the neck and the anterior extremities; and the posterior bundles of these are therefore larger in that requisite degree.

The arrangement of the different parts of this creature appears to me to support the doctrine setting forth the anterior roots of the spinal nerves as exciting motion, and the posterior as conveying sensation. Further dissections may shed a clearer light; this, however, may be sufficient for presuming that comparative anatomy may explain many dubious parts in physiology, as well as, or even better than, experiments on living animals. It may, therefore, be worth while to consider whether the neglect of this most copious source of useful knowledge reflects credit on the profession of this country, and whether groping in the pursuit of science by the random infliction of cruel tortures, is not one of the most humiliating expedients to which men of cultivated minds can have recourse.

I am, sir,

Your obedient servant,

JOSEPH SWAN.

6, Tavistock-Square,
Nov. 1, 1834.CASE OF
MAL- OR TRANS-POSITION
OF THE HEART;WITH COMPLETE OBLITERATION OF THE
GALL-BLADDER.*To the Editor of the Medical Gazette.*

SIR,

EVER anxious to cast my mite into the treasury of useful knowledge, I send you the following particulars of a post-mortem examination, which, whether considered combined, or separately, presents an interest of no ordinary character, — facts of no common observation.

The distinguishing peculiarities of this examination, if viewed apart from each other, are unusual; but looking at them conjoined in the same individual, so far as my observations, and reading, and memory, can carry me, they almost bring me to the conclusion that they are without parallel; but in this respect I wish to speak with modesty, giving place to the more extensive opportunities and range of observation, which locality and circumstances afford to many of my seniors in the profession. In submitting them to publicity, sir, I have chosen the channel of your valuable miscellany, and should you consider them worthy of insertion therein, your early compliance will much oblige,

Your obedient servant,

HILDYARD M. LEPPINGTON,
M.R.C.S.Great Grimsby,
Nov. 7.

Post-mortem examination of J. M. æt. 48, of short stature, broad set, very corpulent, and weighing about 22 stone.

On opening the chest, the first object which presented itself to my notice was the heart, lying directly transverse across the front, just beneath the sternum, having its base to the left and its apex to the right side. The organ was large; though not so when viewed in comparison with the other organs of the body, but taken separately it was. Its structure was soft, tearable, and what some anatomists might call ramollissement; not remarkable for fat, neither had the vessels nor valves undergone any particular lesion. The left ventricle contained some very dark blood, and the right was full; its character and consistence nearly resembling coal-tar, of a

thick, dark, grumous nature. His countenance, a few days prior to his death, indicated some obstruction or imperfect arterialization of the blood; for, on the least exertion, his face and ears were as if they had been dusted with soot, and so continued from half an hour to an hour afterwards. The pericardium was much distended, and contained a considerable quantity of serum. The lungs were somewhat displaced, and the left much larger than the right; they wore a dark mottled aspect, and the cellular structure throughout was expanded with serous effusion, the chest itself containing at least a pint of fluid.

Abdomen.—On examining the abdomen, the stomach, bowels, kidneys, and liver, all presented a flaccid, inactive, and unhealthy condition; their size was more than ordinary, and effusion had taken place throughout the cellular substance more or less connected with these organs.

Liver.—This organ attracted my attention: its appearance was the same as of the heart—large, pale, and soft; but to my astonishment, on looking to the situation of the gall-bladder, I found it completely obliterated, and nothing remained, save a small, soft, dark concretion, tinged with yellow, about the size of a horse-bean, and crumbling beneath the pressure of the finger and thumb—in fact, it scarcely amounted to a concretion—and a condensed corrugated imperforate mass: of course I could not trace any opening into the duct. The abdominal cavity contained, I think, at least two gallons of serum.

One great peculiarity in this case is, that during my professional attendance on him, which was the last year and a half of his life, he never complained of pain anywhere, except occasionally under the left breast, but never in the region of the liver. His bowels were easily acted upon; and if he had one action of the system which was natural, both for regularity and appearance, it was his daily alvine evacuations; sometimes they were rather pale. His tongue was certainly indicative of hepatic derangement, and he frequently underwent a mercurial course, occasionally extending to pytalism.

It may be asked, was there any evident transposition of the heart during life? I frequently made an examination of the chest; but from the feeble

action of the heart, and great density of fat covering the front and sides of the ribs, auscultation was rendered very ambiguous: nevertheless, I well remember more than once, when the pulsation was most distinct, to have observed and mentioned the existence of the fact.

When I saw him at the commencement of his last illness, Sept. 13, he had been bled by the advice of a physician the day previous, and had taken a small dose of elaterium, since which he had become much worse. I found him in a state of complete coma, speechless, with atrophy of the tongue, frequent paroxysms of dyspnoea, great torpor and inactivity throughout the whole frame, the pulsation at the wrist only 40, feeble and indistinct, no secretion from the kidneys, and unable to lie down. He took the pil. hydrag. and pulv. scillæ, with a diuretic mixture, occasionally stimulants, and a blister applied to the back of the neck, which was kept open about a week or ten days, during which time his senses were gradually restored, the kidneys secreted, slight pytalism was produced, but the pulse never exceeded 40; and what is still more surprising, the ensuing week it never exceeded 32 per minute; and during this time he could never assume the horizontal posture. Following up this line of treatment he somewhat improved; his pulse, though feeble, increased in frequency; he could lie down for about two or three hours; his appetite was good, and he was enabled to walk about the house and premises.

During the last fortnight he became anasarous; and on the Friday before his death, he had very sudden and extensive effusion into the cellular substance of the scrotum and penis. I introduced a small trochar, and drew off, guttatim, three quarts of serum. This is not conjectural, because I had it secured as it came, and measured it. Into the penis I introduced the needles, from which operations he became much relieved, but died on the Sunday evening following, suddenly; this I always expected. Had I been disposed to tap the abdomen, it would not, taking the circumstances of the case into consideration, have been justifiable; for my patient was so fat in some parts of the abdomen, as to admit the scalpel three or four inches; and this quantity of adipose substance rendered fluctuation very

indistinct, if at all perceptible; moreover, the anticipated result did not inspire me with sufficient confidence.

Reviewing the history of this case, it furnishes us with the fact, that there was a predisposition to serous effusion, more or less, throughout the system, arising partly from his free habits during the early period of his life, his increasing obesity, and, from the nature of the disease, I suspected some hepatic derangement, although there were no existing local symptoms to guide me in a correct diagnosis, either as it regarded the true character of that derangement, or of its extent. When I visited him on the evening of September 13, it was evident that effusion had taken place within the thorax, the pericardium, and on the brain; and I considered that it had been somewhat accelerated by the previous depletion. Pursuing the line of treatment above laid down, the local symptoms show that the absorbents had been excited, and that some fluid had been removed: his senses returned; his tongue recovered its motion; he was enabled to lie down for two or three hours together; and in this state he continued till within about ten days of his decease, when the exhalants resumed their activity, but with increased power. He became anasarous, and died as above stated.

At the suggestion of Mr. Hewson, of Lincoln, who saw the case with me a few days before death, in addition to the previous treatment, we applied blisters to the legs, from which an amazing quantity of fluid was discharged, and $\mathfrak{z}\text{ij}$. doses of potas. supert. with a few grains of pulv. jalapæ, were given twice or thrice a-day. If I remember right, this mode of treatment is recommended by Drs. Blackwall and Mason Good.

ON BRONCHOCELE IN YOUNG FEMALES;

WITH REMARKS ON THE USE OF IODINE.

To the Editor of the Medical Gazette.

SIR,

To publish his observations in the profession, is the duty of every one, young or old: to resort freely and unabashed to the older and more experienced practitioner, for practical information, is the

duty of the former; and as freely and willingly to bestow that information, is the duty, too, of the latter—as by this means he is fulfilling a part of the useful objects of his humane profession. As a junior in the profession, then, I beg leave, through the medium of your valuable periodical, to insert a few lines on bronchocele in young females.

I am induced to do this from reading the following passage in the excellent Dictionary of Practical Medicine, by Dr. Copland, which is now in the course of publication:—"In a considerable number of cases which have come before me in females, I have never met with any before the period of commencing puberty,—not even in the Infirmary for Children,—although the menses have often been delayed for a year or two, or even longer, when the tumor has appeared at this epoch; and I have seldom observed an instance in this sex unconnected with some kind of irregularity of the menstrual discharge, or disorder of the uterine functions."—Within the last month, I have seen five cases of its occurrence in young females—at least two of the five are nearly grown up; but I have particularly ascertained from their friends that the enlargements have existed since they were six or seven years old; three of the females are at the present quite young; one of them, nine years old, has had the disease three years; the other is six years old, and has had a very large neck some length of time; and the youngest (sister to the last), is not five years old: the neck is not very large, but there is every probability that it will eventually attain as large a size as her sister's. Cases of the disease in older persons are very common indeed; but I do not find that they are at all attended with, or rather, I should say, the consequence, of any irregularity of the uterine functions; and having seen several cases of the disease, I am inclined to conclude, that there is not any very great connexion between this disease and derangement of those functions, although, at first sight, it seems very plausible. Perhaps it is from local causes that cases of bronchocele in young children have not occurred in the metropolitan practice of Dr. Copland; for certain it is, that in some districts this disease is much more common than in others. From my own observation, it

is not common in the parts which I have visited of the counties of Warwick, Stafford, Worcester, and Buckingham. In Hertfordshire, on the contrary, it is very plentiful; and from its being commonly called the "Derbyshire neck," I suppose it is frequent, too, in that county. In some parts of Switzerland and Italy it is very common and endemic; in other parts of the same countries the people are comparatively free from it: it is there generally attendant on that terrible disease *cretinism*, both which have been so fully and ably described by Dr. James Johnson in his "Change of Air." I have noticed, that most of the persons I have seen with the disease are makers of straw-plait. I merely mention this circumstance: it would be difficult even for a theorist to frame a connexion here between the employment and the disease; still, however, a future observer may, perhaps, by some means, explain the fact.

A few days ago, Dr. Hooper told me he had very rarely seen the disease in very young females; and according to the best of his recollection, the youngest subject he had seen with the disease was eight or ten years old.

In the *treatment* of bronchocele, there can be little doubt of the efficacy of iodine: I have seen it used in several cases with the greatest benefit. The little girl who is six years old has her neck very much reduced in size from the iodine treatment. Care has been taken that the medicine should not be administered in such quantities as to produce any of the symptoms of an overdose, such as heat and sensation of weight in the epigastrium, and the other effects of too large a dose, which are so minutely described, in his work on *Materia Medica and Therapeutics*, by Dr. A. T. Thomson. Great caution is required, too, in giving the first few doses of the medicine; for the effects of the same dose, I have often observed, are very different in different individuals, and even in the same individual at different times. That this is the fact, is confirmed by the following passage in the work referred to:—"In irritable habits, even when the dose is not so large as to deserve the epithet overdose, it causes a febrile excitement, often accompanied with nausea, vertigo, and headache, and occasionally symptoms which resemble those of shaking palsy. When these occur, the use of

iodine as a remedy should be suspended." And by the following case of Sir Astley Cooper's, in his *Surgical Lectures*:—"I witnessed, very lately, an instance of an overdose of this substance producing the most violent convulsive symptoms. The quantity of iodine taken was less than that which is often given, but it was an over-dose to this patient. There were forty drops of the tincture in a mixture of six ounces, and he was desired to take three table-spoonfuls three times a-day. He had only taken three-fourths of the mixture when he was seized with the most violent convulsions; his hands, legs, and feet, were kept in constant involuntary motion, and he declared that during the whole night he resembled a person in the act of fighting and wrestling." For this reason, the doses should be very small at first, and gradually increased. There are several tinctures of iodine used, and it is better, after making a trial of them, to adhere to one formula. I have used the tincture made by dissolving two scruples of the iodine in one ounce of alcohol, and have generally begun by giving six drops three times a-day, gradually increasing the dose to fifteen or twenty, according to the age of the person and other circumstances. I have used externally, either the ointment of the hydriodate of potash or of the iodide of mercury: the latter is very easily made, by rubbing equal parts of mercury and iodine together in a glass mortar, and adding half a drachm of the iodide to an ounce of lard.

Its occasional action upon healthy glands is a very important circumstance, and one which should be strictly attended to. Dr. Thomson, in vol. i. p. 344, says, "It is supposed that the nervous plexuses and the great sympathetic nerve are particularly acted upon by iodine; but its chief influence, as an excitant, is undoubtedly upon the absorbents, which it appears to urge to unusual activity, carrying off by their means not only diseased but healthy glands. During the continued use of iodine and its preparations, all the organic tissues (particularly the mammae in women, and the testicles in males) waste; but no gland in the body is exempt from the action of iodine." Again, in vol. ii. p. 393, in the section on Diuretics, he writes thus:—"It is the only substance which seems to stimulate decidedly the absorbents; and their influence, when

thus urged, extends even to the healthy glands: both the mammae and the testicles, free from disease, have, in several instances, nearly disappeared during its administration." It is reasonable to suppose that a medicine which will, through its action upon the absorbent system, reduce an enlargement of the thyroid, or of any other gland, and prevent the future morbid growth of that gland, or act upon healthy structures and prevent their regrowth; I say, it is reasonable to suppose that this medicine, in the same way, may prevent the full development of these parts in persons in whom they have not yet arrived at their full size: therefore, I would ask, is there any danger in giving the medicine for a great length of time to such young children?—because it is evident that the disease had better be left to take its course unmolested than that these healthy glands, when developed, should be absorbed, or any risk arise, from administering the medicine to young children, of interrupting the progress of their natural growth.

The two points, then, to which I would solicit the attention of others, are, 1st, the frequency of the occurrence of bronchocele in young females, and its connexion with uterine disorder; and, 2dly, the propriety or not of giving iodine to young children.

If any persons who may have observed and treated many cases of this disease, will take an early opportunity of communicating the results of their observation and practice to the profession, they will render a service to it generally, and to me in particular.

I am, sir,
Your obedient servant,
T. HERBERT BARKER.

Redbourn, Herts. Nov. 10, 1834.

EXTRACTS FROM A

JOURNAL OF NATURAL HISTORY;

Kept during a Voyage from England to New South Wales, and on the return to England, by way of Batavia, Pedir Coast, Singapore, &c.

By GEORGE BENNETT, ESQ.

(For the Medical Gazette.)

On the 10th of March, in latitude 14 min. south, and longitude 20 deg 7 min.

west, at 3 P.M., I captured by the towing net a very fine specimen of *Janthina*, to the shell of which several very small *Anatifa* were attached by a very small peduncle. On placing the specimen in a glass of sea water, the animal floated by the vesicular appendage attached to the foot, and which was protruded in a similar manner when the animal was in the net, and being also never seen retracted when other portions of the animal were so, I do not consider the animal has the power of doing so: when this appendage was touched with the finger, the animal (when alive) retracted itself, but the vesicles remained unmoved even in the slightest degree. Cuvier seems to consider that the animal has not the power of emptying or filling it with water, but observes regarding the capability of the animal withdrawing itself into its shell, "il peut seulement le comprimer en le faisant rentrer dans sa coquille, ou l'abandonner à son élasticité naturelle en l'en laissant sortir."—(*Sur les Mollusques*, 4to. Paris, 1817.) It exactly resembles in appearance *froth*, and merits the appellation given to it by Fabius Columna, of *Spuma cartilaginea*; for, as Cuvier observes, although like foam, "leur parois sont quelquefois comme de cartilage, assez dures même vers la racine et la partie postérieure; plus molles, plus membraneuses, en avant et à l'extrémité. Dans d'autres individus, je les ai trouvées plus étendues et entièrement membraneuses."—(*Loc. cit.*)

It is mentioned by Cuvier that some individuals have been found in which this vesicular appendage has been found wanting, and considers that the only difficulty they experience is in keeping themselves upon the surface of the water; but as I have captured specimens without this appendage by the towing net, the similar method by which those with it have also been taken, I must only infer that they can float on the surface of the water equally with or without it, although it must be naturally supposed that the animal and its shell cannot be retained so long on the surface without as with it.

The shell of this animal is of a delicate and pretty form, and of a greater or less deep violet tint; some were white in a great proportion over the upper surface of the shell, and these shells are only found floating on the water at great distances from the land: it has occa-

sionally also, I believe, been captured about sea-weed, but this is of comparatively rare occurrence.

The animal is among the *Tracelipodous* animals.

The animal, with its beautiful lilac-coloured shell, and transparent bubbles, afforded a very interesting object when viewed floating in a glass of water: the little barnacles about its shell also displayed vitality, by thrusting out and withdrawing its minute tentaculæ in a beautiful stellated form, somewhat resembling the zoophytes which produce the elegant corals.

When a fly perched and ran about the vesicular appendage, which projected above the surface of the water, it did not produce any effect, so as to cause that appendage (allowing the animal to have the power) to be retracted within the shell.

On the animal being touched in ever so slight a degree, it produced the effect of causing it immediately to withdraw itself into the shell, and even at first on any person moving near the glass of water in which it floated; but then the frothy appendage always remained stationary. It was nearly two hours after it had been placed in the glass of water before the animal became so bold as to protrude the whole of the upper portion.

In the evening I found the specimen of *Janthina* dead.

The view of this pretty shell and animal, together with the parasites attached to it, excited much interest by their beautiful appearance, by far exceeding either the engraved representations, or specimens preserved in alcohol.

March 16th.—On looking this evening at the specimen of *Janthina* in spirits, I found the shell and soft parts, which before had been suspended in the alcohol by the vesicular appendage, sunk to the bottom of the bottle, and the vesicular appendage detached from the animal floating still upon the surface: it was not separated by any injury, as the bottle had not been moved since the last time I saw it suspended, as when first placed into the spirits.

In a note, at page 108, vol. ii. of Lyell's Principles of Geology, it is mentioned that Mr. Broderip possesses specimens of *Janthina fragilis*, bearing more than one species of barnacle (*Pentelasma*), presented to him by Capt. King and Lieut. Graves. One of these

specimens, taken alive by Capt. King far at sea, and a little north of the equator, is so loaded with those cirrhipeds, and with numerous ova, that all the upper part of the shell is invisible.

At 6, P.M. a number of the luminous rose-coloured *Medusæ* were taken.

At 8, P.M. several *Phyllosoma* of the species *commune* et *clavicorne*; and several triangulated crustaceous animals in some degree resembling young specimens of *Hylæa dentata*, and a small bronze-coloured fish.

There are occasional sparklings and flashes of light after dark occasioned by *Pyrosoma*, *Medusæ*, *Salpæ*, and other luminous molluscous animals; but on placing the towing net over the stern of the ship where the luminous appearance was strongest, it appeared to pass through the luminous masses, but not a specimen was caught, which I can only attribute to their swimming deeper.

At 9, P.M. a very large quantity of *Phyllosoma*, (species *commune* et *clavicorne*.) but all of small size, were in the net: there were at least several hundreds, and a repetition of throwing the net overboard always brought up large quantities in a short time, so that large shoals must have been near the ship at that particular time. This I have often remarked as occurring with the *Pyrosoma*, *Smerdis*, *Salpæ*, &c.

March 12th.—Fine and calm weather. Lat. 00° 52' N. and long. 21° 15' W. A large bird of a heavy flight, like a gannet, was observed at some distance from the ship, and was not sufficiently near to enable me to ascertain what it might be.

Two of the "Stormy Petrel" (*Procellaria pelagica*.) "Mother Carey's chicken" of seamen, were also flying about this morning. I observe in a newspaper that "in December, 1833, by reason of the late heavy gales at sea, the stormy petrel has been seen on the river Thames above London, and shot."—Although we now saw these little harbingers of wind and storms in the latitude of calms, &c. yet, when in higher latitudes, with strong south-west winds, not one was seen, or any indeed even to the Channel, except these just mentioned.

14th.—Fine weather, with light airs from the northward, and calms. Lat. 1° 27' N. and long. 22° 34' W. Several stormy petrels were flying about the ship; and in the evening I caught a

small luminous *Salpa*, which gave out, when touched, a beautiful bright light, not diffusing itself over the animal as I have usually observed, but in rapid streaks like lightning, having a fine effect: it was so brilliant that the phosphoric light could be distinctly seen even by lamp-light, and the more the animal was disturbed, there was an increased vividness of light, but invariably in the streaked form just mentioned.

16th.—Lat. 1 deg. 38 min. north, long. 23 deg. 30 min. west. A white shark was seen about the ship early this morning, with the usual accompaniments of pilot and sucking fish.

At 6, p.m. I caught a specimen of the molluscous animal allied to *Leptocephalus*.

At 8, p.m. I took several small luminous transparent *Medusæ* and *Salpæ*; *Alima hyalina*, *Smerdis armata*, *Phyllosoma commune*.

There were also three specimens of *Cleophora*: these shells are so easily broken, that the greatest care is required to take them out perfect from the net.

Both at 8 and 9, p.m. large quantities of small specimens of *Phyllosoma* were captured in the net.

17th.—Lat. 2 deg. 00 min. north, long. 24 deg. 22 min. west. At 4, p.m. I caught another of the mollusca allied to the *Leptocephalus*, and the first I ever yet procured during daylight: this specimen measured $6\frac{2}{3}$ inch in length, and half an inch in the greatest breadth: there was a continuous black line (very narrow) both at the upper and lower part of the animal, and another similar, extending the whole length of the centre. The animal was alive when caught, but died almost immediately after. On its death, the black lines were very indistinctly seen.

At 8, p.m. I caught some luminous *Salpæ* and *Medusæ*. There was also a specimen of *Cleophora*; and two specimens of minute spiral shells of a reddish brown colour. Some of the *Hyalæ tridentata* were also taken.

18th.—Lat. 2 deg. 20 min. north, long. 25 deg. 26 min. west. At 11, a.m. I found in the net a fish measuring five inches in length; a dark blue line on the upper part of the back, remainder of the body silvery. There was also another fish, $1\frac{1}{2}$ inches in length, with purple back, and silvery sides and abdomen; two spines at the posterior and two at the anterior part of the branchial

apertures: the tail was spotted with black.

There was also taken a very minute specimen of *Janthina* and several *Porpita*.

22d.—Lat. 7 deg. 12 min. north, long. 32 deg. 33 min. west. At 7, p.m. until 10, p.m. large quantities of the *Smerdis communis* et *armata* were caught, evidently being large shoals of them about the ship. A small flying fish was also caught.

31st.—With the Sargasso weed a large crab was caught.

At 8, p.m. I captured in the net several small luminous transparent *Medusæ* and *Salpæ*, and also several small bronze-coloured fish, lat. 22 deg. 16 min. north, long. 41 deg. 6 min. west.

April 1st.—At 8, p.m. among some Sargasso weed in the net, I found two specimens of *Sepia*, of a purplish colour; two specimens of the "bronze-coloured fish," one $3\frac{1}{2}$ inches long, and $\frac{7}{8}$ of an inch at the greatest breadth.

At 9, p.m. with some weed, was a small specimen of *Leptocephalus*.

2d.—Ther. 70 deg. to 74 deg. Lat. 24 deg. 33 min. north, long. 43 deg. 22 min. west. I found a number of crabs and shrimps among the weed.

A small dolphin was caught this morning: in its stomach was a half-digested flying fish. Several long slender *Filaria* were also found there.

Among the Sargasso weed I found circular clusters of yellow ova enveloped in a transparent gelatinous substance, and which may probably be those of *Seyllæ pelagica*.

3d.—Ther. 71 deg. to 74 deg. Lat. 26 deg. 9 min. north, long. 43 deg. 00 min. west. At 8, p.m. I found some Sargasso weed in my net; several of the small fish similar to those before caught; and one also short, thick, and of peculiar form.

4th.—Ther. 69 deg. to 72 deg. Lat. 28 deg. 6 min. north, long. 42 deg. 46 min. west. On the Sargasso weed, besides numerous small crabs (some of which had black ova in the usual situation,) were also green, yellow, and red-coloured shrimps. Many of the leaves and berries of the Sargasso weed were encrusted by some crustacea of a minute kind.

5th.—Ther. 68 deg. to 72 deg. Lat. 29 deg. 17 min. north, long. 42 deg. 57 min. west. At noon, among a mass of Sargasso weed, in my towing net, I

found a large specimen of a crab prettily mottled, with reddish brown and white.

There was also a fish of a whitish colour, with irregular black spots: it was of large size.

At 1, p.m. I captured in the net, with as usual abundance of Sargasso weed, a fine specimen of *Syngnathus*, or pipe-fish. It was of an olive colour above, and a beautiful golden beneath, with white lateral marks nearly the whole length of the body. It survived for some time out of the water, after it was caught.

At 3, p.m. I caught another large crab similar to the one mentioned above, but not quite so large, among the Sargasso weed.

Soon after I found in the net a fine and large specimen of *Physalis pelagica*, adorned with the usual beautiful tints, but not so vivid as I have usually seen them. The tentacule were for the most part broken, that is, the long filiform ones, the short and thick kind remaining perfect: the longest of the former were nearly four feet. The length of the bladder portion of the animal was $5\frac{1}{2}$ of an inch; and the greatest diameter 3 inches, and the greatest height $3\frac{1}{2}$ inches.

The application of cold water seems to renew the irritative effects of the acid fluid emitted from the tentacule of this mollusca, even when the first pain has in some degree subsided.

At 5, p.m. besides a quantity of shrimps among the weed, there was also a small triangular *Salpa*.

At 6, p.m. I caught among the weed a very small fish, not unlike an embryo specimen of the "flying gurnard," being of a red colour, with black marks.

6th.—Lat. 30 deg. 21 min. north, long. 44 deg. 7 min. west. About noon, among the Sargasso weed, with as usual numbers of shrimps and crabs, I caught a *Syngnathus*, or pipe-fish, similar to the one caught yesterday, but smaller in size.

At 1, p.m. I caught, with the weed, another of the embryo fish resembling the *Trigla volans*, or flying gurnard, and similarly marked to the preceding, and which expanded its pectoral and ventral fins in a very pretty manner when placed in spirits.

A small *Sepia* of a fine purple colour, with dark red spots, was also caught; and a large crab, mottled with reddish

brown and white, similar to those previously captured.

At 5, p.m. the net contained among the weed a purple *Sepia*, similar to those caught before, together with numerous crabs and shrimps; and a small fish, with purple back, and silvery sides and abdomen.

7th.—Ther. 66 deg. to 68 deg. Lat. 30 deg. 36 min. N. long. 43 deg. 22 min. west. At 2, p.m. I found among the weed in the net, besides several species of crabs and shrimps, and one of the small purple *Sepia*, with dark red spots, a large crab, similar to those previously caught, but with a mass of ova in the usual situation: attached to the upper part of the shell was an *Auatifa*, of a blackish colour, partly edged with white. There was also a minute fish, of a beautiful purplish colour.

At 3, p.m. I found among the weed another crab, mottled with reddish brown and white, but of much larger size than the preceding specimens caught: it had also a parasite attached to the dorsal shell, similar to the one before taken, but smaller.

Besides the great numbers of small crabs and shrimps seen about the masses of the Sargasso weed, several of a very pretty striated species of *Auatifa* were seen attached to it.

A CASE OF CONGENITAL DEFICIENCY OF BOTH THE UPPER AND LOWER EXTREMITIES*.

By J. F. E. HARDY, M.D.
Of Ashville, North Carolina.

THE subject of this deformity is a young woman, aged about 20 years. She was born without either upper or lower extremities, the situation of which is merely occupied by small rounded projections. The stumps of the shoulders are remarkably small and short; those of the thigh are much larger, but are not more than two inches in length. I think her mother has had twelve children, but she is much larger than either of her brothers or sisters. She is, indeed, of a full and plump habit, and possesses a peculiarly lively disposition.

* Communicated in a letter to the Editor of the American Journal of the Medical Sciences.

Her power of locomotion is remarkable. She can transport herself over the floor with considerable ease, which she does by submitting her body to a kind of rotatory motion alternately from right to left, and the contrary. By confining the handle of a broom between her chin and shoulder, she can sweep the floor with considerable dexterity. She can also sit erect, lean back, or rock herself in a chair, as well as another person; and when any thing is given her, she makes a sign for it to be placed upon her shoulder. If it be any solid article of food, she eats it from that situation.

Her hips and nates are remarkably full and large, and are almost square. Her breasts are also voluminous, and remarkably plump, presenting all the characters of the mammæ of a stout young female of her age. Her catamenial discharge is regular, and of the natural quantity.

The annexed woodcut will serve to convey a more accurate impression of her general appearance, than could be communicated by any description.

THIS defective evolution of the extremities has been observed under various degrees. Saxtorph* has reported a case in which even the os innominatum was absent; and one has been de-

scribed by Martin*, in which the outer third of the clavicle was wanting.

More frequently, the pelvis and shoulders are properly formed, but the rudiments of the extremities merely represent small excrescences or projections, covered with a smooth skin, and with or without nuclei of bone within. Cases of this kind have been reported by Buchner, Duverney†, Isenflamm‡, Dupuytren§, and others.

Still more frequently there is an absence of the arms, forearms, thighs, and legs; but the fingers and toes exist in a rudimentary condition, and are implanted directly upon the trunk of the body; or the hands and feet are still more perfect, but have the same kind of connexion. Examples of various modifications of these conditions have been communicated by Caldanij, Dufraigne¶, Dumeril**, Dumast††, Meckel‡‡, Flachslan§§, Bouchard, and others.

In all cases of the kind, the defect is owing to an arrest of development taking place before the different parts of the fœtus are evolved; and it will vary in degree, according to the advances made by the process of development, at the period at which the interruption takes place.

ANALYSES AND NOTICES OF BOOKS.

expended on the present edition of the work before us; and while we give the learned editor full credit for his assertion, we may safely add, that they have not been expended in vain. Every page bears evidence of the care with which the revision has been conducted, and the mass of additional matter which has been either dove-tailed into the text [with brackets of acknowledgment], or appended in the shape of notes, is really prodigious. Another great improvement is, that the number of volumes is reduced from five to four—a change which appears to have been accomplished, notwithstanding the additional matter, by increasing the size of the page, and the employment of a type which is exceedingly distinct, and yet marvellously absorbing.

The work is altogether completely modernized, containing all the improvements and novelties in medicine down to the latest date. As an illustration, we observe an account of the *Acarus scabiei*, quoted from the number of this journal published the 4th of last month; and here we must also express our approbation of the minute, and apparently very faithful, manner in which references are made to authorities. The *Cyclopædia of Practical Medicine*, the *Edinburgh Medical Journal*, and the *London Medical Gazette*, are incessantly quoted on points of interest. The "Study of Medicine" is thus brought up to the highest standard of the present day, and, as a work of reference at once systematic and comprehensive, has no rival in medical literature.

We shall probably insert from time to time some of the more interesting notes; at present we subjoin the following as a specimen. It contains the particulars of a very curious case, in which numberless portions of tape-worm have been voided from the bladder—perhaps in consequence of a fistulous communication between this viscus and the intestinal tube?

Case in which portions of Tania have been, and continue to be, voided from the Bladder.

"The Editor, through the kindness of his friend, Dr. Docker, late of Canterbury, has been furnished with the particulars of a young woman, upwards of twenty years of age, who has been under the care of Mr. Law, of Penrith, in Cumberland, since October 1830, and has discharged several

thousand portions of *tania* from the *meatus urinarius*. In a letter, dated Penrith, Aug. 29, 1833, Mr. Law states, that "she first felt a sensation like that of a rupture of the bladder, when in the act of stooping to cut a corn, in August, 1829. From that time she had discharges of bloody urine occasionally, with the sensation of something moving in the bladder, more particularly so after each evacuation, and had concluded that this was a worm. However, no mention was made of this to any one, although her health was impaired, until I was called to attend her for an attack of laryngitis, in October, 1830. Blisters being used, brought on retention of urine, with cystitis, which rendered the use of the catheter necessary. After this had been conquered, she mentioned her feelings and apprehensions to me, which for some time I treated as imaginary, till at length, from the greatly disturbed state of the mucous membrane of the bladder, evidenced by deposition, in large quantities, of a white sediment in the urine, I was led to try the exhibition of spirit. terebinth., both by the mouth and injection. Great irritation ensued, but a small portion (about eight joints) of *tania* was discharged, per urethram, alive. This led me to the determination to try the effect of opiate solutions, frequently injected into the bladder, which, by keeping the worm constantly under its influence, might destroy it. This, persevered in for three days, answered the purpose; all motion of the worm ceased; and, by an expansion of the urethra, its discharge was effected in large quantities, but in so decayed and broken a state that its parts could not be numbered; but I am certain that there could not have been less than 2000 joints. With these there was much hæmorrhage, also membranes and other substances. From this date (January, 1831) to the beginning of April of the same year, there were not indications of more *tania*; yet the urine was generally tinged with blood, and deposited the white sediment in less quantities than formerly. During this period, an anodyne injection had been used almost daily, as the irritation of the bladder was considerable. At this time she again felt the motion of *tania*; and I again resorted to frequent opiate injections, but without success for some days, and then determined upon the administration of spirit. terebinth. by the mouth; a teaspoonful of which was taken on the morning of the 18th of April, and which passed by the bladder in an hour and a half, bringing off some portions of the worm in a recent state, with a net-like membrane. From this date to September 20th, there were passed from the bladder, per urethram, 1230 joints of different sizes, from

one-third to the eighth of an inch in width, and which were all preserved, with portions of a net-like membrane, and fungi, either like the liver or the muscles of a fowl, and sometimes of a fleshy fibrous substance, having the appearance of the muscular coat of the bladder, with a shaggy surface on one side, resembling the villous coat of the intestines. These were brought away almost daily, while the urine diminished in quantity, rarely exceeding four ounces in twenty-four hours. A pause ensued from the last date to November 16th, of the same year; during which time neither worm nor substances passed off, but the fluid discharged was bloody, and always highly offensive. On this day the spirit. terebinth. was again administered, and brought off in an hour two small pieces of net-like cellular tissue, with nine joints of middle-sized worm interwoven with it. From this time to January 18, 1832, there were 773 joints preserved, of different sizes, and these were generally accompanied with membrane and fungi of different kinds. From this date to March 27th, there were no portions of tænia passed; but on that day the spirit. terebinth. was again taken, and before May 1st, 853 joints passed, making a total of 2865 now in my possession, besides a very small and apparently perfect worm of twenty-nine joints. During the period mentioned there have been at different times profuse hæmorrhages from the intestines, surmised to arise from the ascending colon, which have reduced my patient to a very weak state. She is now (August 23) in tolerable health, but again bringing away, from the use of the spirit. terebinth., more tæniæ. On the 21st instant there came off four joints of a small worm, with two small fungi.

"Among the singular and unaccountable phenomena accompanying this affection, is the rapidity with which spirit. terebinth. now passes from the stomach to the bladder. It is invariably felt in the bladder in less than twenty seconds from being taken; and its evacuation, per urethram, rarely exceeds two minutes: on one occasion it passed in one minute and a quarter; and from the recent appearance of the worm and fungi, seems to separate them in passing.

"Mr. Docker is in possession of some specimens of the worm, fungi, and membranes."

In a later communication to Mr. Docker, the following additional particulars of this remarkable case are given:—

"Tuesday Evening, April 15th, 1834.

"I am very sorry that I have hitherto been unable to send you the specimens of

tænia, &c. as you requested, and now do so in a great hurry, in order to avail myself of a gentleman's visit to London, who has kindly offered to take a box for me. My engagements, during the absence of my young man at Edinburgh, were so many, that I could not find time to make a selection of my tæniæ, &c. for Mr. Cooper until his return, and now send you a few specimens of the different sizes, with those of the fungi, muscular substances, as I call them, and the net-like membranes. I also inclose a copy or two of my memoranda regarding the effects of the spirit. terebinth., and also the results, for a few days (which may be taken as a fair sample of the whole). You will see by the former the rapid passage of the spirit. terebinth. from the stomach to the bladder, and the increase of that rapidity by degrees to its present point, about eight seconds, and its evacuation in less than a minute, when the orifice is not obstructed by much substance. This is an interesting phenomenon, and worthy of the particular attention of the anatomist and physiologist. As you have been an eye-witness, with many other medical men, it is a fact which can admit of no doubt. The second phenomenon is also remarkable and interesting: the small secretion of fluid by the kidneys. This is always increased by the spirit. terebinth. on the day following its exhibition."

By the table which is annexed to the communication, it appears that the dose of turpentine always produces a peculiar sensation in the bladder in a few seconds, and the evacuation of portions of worm in a few seconds more.

A Treatise on the Diseases of the Chest and on Mediate Auscultation. By LAENNEC. Translated, enlarged, and improved, by JOHN FORBES, M.D., &c. Fourth Edition.

It would be superfluous, we think, to offer our readers any detailed account of this justly-celebrated work. The appearance of a new and cheaper edition shows the demand in which it has been held among the booksellers—a good test of the increasing popularity both of the subject and the treatise.

Dr. Forbes has introduced a great quantity of new matter in the notes, and has availed himself freely of the labours of his learned contemporaries: to Dr. Hope and Dr. Williams, we perceive, he acknowledges himself specially indebted, and in return recommends their respective works to all who are interest-

ed in the modern method of investigating chest diseases. Appended to the chapter on the *motions and sounds of the heart*, we find an excellent summary of all that has been said of late by various theorists and experimentalists touching this still obscure subject. What Dr. F. says, in conclusion, relative to Magendie's theory, we shall extract.

"Since the first announcement of M. Magendie's views respecting the causes of the sounds of the heart, two years since, by M. Pigeaux, this distinguished physiologist has himself published his opinions on the subject, and which, if they were formerly and are again correctly reported, seem to have undergone a very important change. (See a translation of M. Magendie's memoir in the *MEDICAL GAZETTE*, June 28, 1834.) He now attributes the *first sound* to the shock of the apex of the heart against the walls of the chest during the *systole* of the ventricles, and the *second sound* to a similar impulse of the anterior surface of the right ventricle during the *diastole* of the ventricles. The principle of the generation of the sound is indeed still the same, but the causes of the individual sounds are in some degree reversed. Against the truth of M. Magendie's principle many arguments may be adduced, and even, it would appear, some well-ascertained facts. I shall here state a few of these, for the substance of which I am indebted to my friend, Dr. Williams, the ingenious author of the first portion of the present note.

"1. In the experiments by Dr. Hope, the impression on Dr. Williams's mind is, that he distinctly heard the two sounds of the heart when this organ was removed from all contact with the thoracic parietes and the pericardium, and when the constant and close apposition of the stethoscope precluded the possibility of any sound being produced by any shock against it; and it will be seen hereafter that M. Bouillaud's conviction is similar.

"2. To say nothing of the inconclusiveness of any arguments deduced from phenomena elicited under such an unnatural condition of things as existed in these experiments, it may be remarked, that the third and fourth are subject to fallacy, inasmuch as 'the sonorous bodies' and 'the sternum of the goose' might have given rise to sounds in consequence of the existence of an interval between them and the heart; a state of parts very different from the natural, in which the heart and the walls of the chest are in apposition, and which unnatural state of parts might have permitted the organ to communicate a shock to the bodies, utterly impossible in the natural state.

"3. The facts adduced in the memoir after Exper. 4, and the 5th and 6th experiments, merely indicate that the sounds of the heart cannot be heard through a considerable layer of air, water, or healthy lung—facts long known; but M. Magendie has yet to prove that any injection of air or water, separating the heart from the walls of the chest, will prevent these sounds from being audible over the left clavicle.

"4. How will M. Magendie explain, in accordance with his views, the incontestable facts of the increased loudness and diminished impulse in dilatation, and the converse in hypertrophy? or the intensity of the sounds in the carotids, and at the top of the chest, in aneurisms of the arch of the aorta and innominate, in which cases they are often heard more distinctly than in the region of the heart itself?

"It would further appear, that since M. Magendie's paper was read before the Institute, M. Bouillaud has performed a series of experiments, with the same object, but with results the reverse of those announced by Magendie. The results of M. Bouillaud's experiments was, that he could always hear the two sounds of the heart although there was no point of contact between the organ and any portion of the walls of the chest. He, indeed, found that the friction of the heart against the end of the stethoscope gave rise to a particular sound; but this (merely a sound of rubbing) was so very different from the natural sound of the heart that the two could never be confounded. It was, moreover, ascertained that the momentary pulsation of the empty organ, after it was separated from the body of the animal, was accompanied by no perceptible sound. M. Bouillaud's own opinion respecting the cause of both the sounds, is, that they are owing to the play of the valves of the heart. (*Journ. Hebdom.* quoted in *Med. Chir. Rev.* July 1834.) In reference to this opinion of M. Bouillaud, as also to that of Dr. Hope, I would observe that they both possess a degree of probability in my mind over all those which attribute the two sounds to *two* different causes. Although certainly characteristically different, yet the two sounds have so great a similarity, and are so allied in time and place, that I cannot readily bring my mind to believe that they do not both depend upon one and the same cause slightly modified, or, at least, on the different play of the same parts. But the whole subject wants fresh investigation and the institution of a new set of experiments on large animals,—an investigation which cannot be entrusted to better hands than those of Dr. Hope and Dr. Williams."

The value of the present edition, we

should add, is greatly enhanced by the ample bibliography annexed to each article; and, on the whole, we must say, that the style in which the work has been brought out, is highly creditable to all parties.

Elements of Anatomy. By JONES QUAIN, M.D. Third Edition, revised and enlarged.

WE gave our opinion of this work on a former occasion, and have now only to express our satisfaction, that what we then said has been fully borne out since by the public favour. It is a strong testimony to the merit of these Elements, that two editions have been already exhausted, and that a third comes forth in an enlarged form. The view of general anatomy in the introductory chapter, is full, clear, and comprehensive; and the arrangement of the several compartments of the descriptive portion is as convenient as can be wished. The book, besides, is furnished with good indexes, and ample references to works of authority, native and foreign.

The Surgeon's Practical Guide in Dressing, and in the methodic application of Bandages. By T. CUTLER, M.D.

THIS appears to be a valuable little treatise. The author seems to have spared no pains in procuring correct descriptions of all the surgical apparatus at present employed in bandaging and dressing, both at home and abroad. He has given numerous illustrations, in the form of well-executed woodcuts, and has altogether produced what we conceive to be a very useful, and by no means an expensive, publication.

A Manual for Students who are preparing for Examination at Apothecaries' Hall. By JOHN STEGGALL, M.D. Sixth Edition.

WE are by no means favourable to the short cut to learning usually presented by a *vade mecum*; but we must confess that Dr. Steggall's book constitutes an exception to the general censure. We have here much that is useful in a very small compass, very methodically arranged, and clearly explained. We do not advise young gentlemen to trust to

this, or any other "manual," for their full acquaintance with the subjects to which it relates, but are satisfied, nevertheless, that they will find in it both a useful index to what they ought to know, and "a brief chronicle" of the points they are most likely to be examined upon when they present themselves before the Court of the Worshipful Society.

Hahnemannism.—A Popular View of Homœopathy. By the Rev. THOMAS EVEREST, Rector of Wickwar, Gloucestershire.

THE following cool anathema met our eye as we opened this "popular" pamphlet just published by our *reverend* advocate of homœopathy. We give the passage for the amusement of our readers—for amuse them it must, unless their nerves be peculiarly sensitive.

"*Woe thrice-doubled to him who is wise in his own eyes, who knowing that a perfect and complete system (viz., of course, homœopathy) claims attention on account of the multitude of its cures, &c. &c. dares to quoit it down stairs like a shore-groat skilling, &c. Be a far lower, deep, and a far darker shade of infamy, the portion of that merchant of miseries who would delay inquiry, because, if it proved true, he might fall short of some of those rascal counters with which agony fees his unwholesome palm. Cleave the leprosy of Gehazi for ever to him who would sell the mighty space of his large honours(?) for as much trash as may be grasped thus. But there is no such man; kind heaven forbid it! lest the curse of Cain once more affright the world!*"

WE make no comment on this *spirited* extract, but would merely ask whether the Rev. Mr. E. might not better reserve his zeal for some other cause. The "Ereles," or Boanerges vein, we can assure him, is not the fittest for preaching Hahnemannism in England: and the method of arguing by *commination*, we would remind him, has been for some time out of fashion in this country.

For the favour he has done us in printing at length our remarks on a former epistle of his, he has our best thanks: we are only sorry we have made so little impression on him.

MEDICAL GAZETTE.

Saturday, Nov. 15, 1831.

"Lcet omnibus, llet etiam mihi, dignitatem
Artis Medice tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL PROVISION FOR THE
POORER CLASSES IN THE ME-
TROPOLIS.

THE accident to which we alluded last week—the loss of life for want of timely aid from a parish surgeon—is fresh still in our memory. We fear it is but one of many cases which are constantly occurring in this great metropolis; but of which little notice is taken, from their very frequency. It can scarcely be otherwise in a population so vast, the pauper proportion of which is so considerable, and where the supply of regularly-appointed practitioners allotted to the duty of attending on the poorer classes is so utterly insufficient. Take, for example, the great parish of St. Pancras, where the population exceeds 110,000, and where the workhouse alone usually contains above 1000 inmates: what is the extent of medical provision for the poor, allowed by the parish authorities? For the Infirmary of the workhouse (which commonly contains about 200 patients) there is a resident general practitioner, and, we believe, one physician, who visits there occasionally. For the out-paupers scattered through this extensive parish, which reaches nearly to Highgate in one direction, and to St. Giles's in another, there are *three* surgeons. These gentlemen are, of course, liable to be called upon at any moment, and often obliged to attend at distances most unconscionably harassing; while the pittance they receive for their labours is niggardly in the extreme.

This system of administering relief, is also wretchedly bad in another respect. Before a pauper can be attended

by a parish surgeon, there must be an "order" procured, to shew that the unfortunate patient is entitled to be treated medically at the parish expense; and when that requisite is complied with, the surgeon, most probably, is otherwise occupied. Thus it was with the case of last week: some hours were lost before a little liniment could be procured for the burnt sufferer, through the necessary "order," and several more elapsed before the surgeon could attend in person: when he did arrive, it was too late.

There are few who admire more than we do, that *laissez faire* principle—that dislike of interfering with the concerns of the people, unless where it is imperatively necessary—by which our government is characterized above that of all the other states of Europe: but we think that, in certain instances, the observance of the principle may be carried too far. Of late, indeed, there have been measures adopted which tend to throw the poorer and more helpless classes of society more on their own resources than ever, and that apparently without a due consideration of their ability to bear the change. Persons high in authority have denounced the system which has hitherto prevailed, of ministering to the corporal wants of the destitute, and have openly attacked the benevolent institutions of the country—even those supported by voluntary contributions—as hot-beds of penury and demoralization. This may be very philosophical in theory, but it is very absurd in practice. The Malthuses, and the utilitarians of every description, may generalize as much as they please, on the advantages that must accrue to the state from the abolition of hospitals and workhouses; but poverty and disease will not vanish at the bidding of the greatest sage among them. In their prodigious zeal for the regeneration of mankind, the *philosophes* of France, about the period of the first revolution, seriously entertained

the notion of destroying all hospitals, infirmaries, and asylums, in that country; but luckily they took a little time to think: a commission was appointed to consider whether it ought or ought not to be done, and the verdict of the enlightened jury—it really was an illustrious one, including, as it did, the names of Laplace, Daubenton, Lavoisier, Bailly, and Darcet—was, that hospitals could not well be dispensed with, but were proper objects for the attention of government.

In this country the government does nothing for hospitals—merely recognizing the existence of some of them: yet, so far as such institutions can alleviate the immediate distresses of the humbler classes, thanks to the benevolent spirit that animates the higher orders in the community, nothing is wanting. It is therefore, perhaps, so much the better that there is no interference on the part of the state. The generous principles of the more fortunate members of society are thus directly enlisted, and actively engaged in behalf of their poorer brethren; and a sort of family feeling prevails among us—the foundation, no doubt, of much of our nationality—to which nothing comparable is readily found among our continental contemporaries. Would that an equally anxious desire were entertained by the poorer portion of the population, to be enabled to *aid themselves* by a provident regard for the future! In the absence or the withdrawal of aid from without, the existence of such a principle were better than treasures.

The self-supporting dispensary system is that which, above all others, seems calculated to meet the emergency, and to suit the circumstances of the times. It is reducible to practice even among the bluntest: it has been tried in different provincial towns, and found to have the most promising, the most satisfactory results. Nor are the direct

benefits arising from it to those who have embraced it, more conspicuous than the advantages which it confers upon the profession, and the invaluable boon it bestows on the country at large in the shape of sober, steady, and provident citizens. But we have so often and so fully expressed our approbation of the system, that any thing we should now add regarding its general merits must have an appearance of superfluity: it were, at the least, a tale twice told.

Entertaining such sentiments as we do of the value of the “self-supporting” principle, and particularly with reference to the actual wants of the community, we cannot but wish that the system had a fair trial in the metropolis. We are not ignorant of the fact that it has been attempted to be established in one or two districts of the town; but a *fair* trial it has not yet had. The numerous dispensaries and benevolent societies about London, and the medical services therein so liberally tendered, are, we know, a main impediment to setting up the Smithian system on a proper footing. The motives for its adoption here do not press with any thing like the force which attends them in places less abundantly stocked with charitable institutions, and a *corps medicale* full to overflowing. But all this constitutes only a difficulty, not an impossibility, in the way of erecting dispensaries on the excellent principle in question,—a difficulty which will be ultimately surmounted by a steady adherence to the grand object in view, with a fixed resolution to attain it. No *compromise* in the matter can be productive of any good: and we suspect it has been owing to a mistake of this kind that some reasonable progress has not already been made in establishing the system in the metropolis.

We understand that certain very questionable modifications of Mr. Smith's plan have of late been adopted in London. *Ticket-selling*, for example,

has its partisans among those who perhaps mean well, but are imperfectly acquainted with the only correct principles on which the self-supporting dispensaries can repose. This plan of selling tickets *to persons in sickness* is one of great facility of application, but at the same time fraught with gross abuses. It is a plan which can lay no claim to the merit of fostering that provident feeling in the poor which is so desirable on every account: nor can we see in it the least protection for the interests of the profession at large. It opens the door to abuses on the part of certain medical men, who, having little or no practice, find ticket-selling a convenient mode, however degrading it may be, of obtaining some; and such persons, as may be supposed, will not be very scrupulous as to the parties to whom the tickets are sold,—most probably to persons quite able to remunerate their medical attendants in the ordinary way, but who are induced to purchase tickets through a spirit of niggard economy. The plan, in fact, thus modified, resolves itself into one for selling cheap physic, to the injury of the profession, and the ruin of the system on which it professes to be founded.

Members of a self-supporting dispensary should only be admitted *while in health*; and their fitness for admission should even then be inquired into by a competent committee, who would exercise impartial justice between the candidate and the medical man. Institutions of the self-supporting description, it should be recollected, are designed to supersede charity, and to cultivate a provident feeling in the poor, by enabling them, when in health, by small periodical payments, to insure the privilege of attendance in sickness: but at the same time, it should be borne in mind that they are intended for the benefit of *the poor only*, and should be strictly confined to their use by proper arrange-

ments, scarcely admitting of any infringement; otherwise the interests of the profession at large must assuredly suffer.

The true principle of the self-supporting dispensary system has not yet been fully developed: the advantages which will arise from it, if it be duly acted upon, are, we think, as yet but imperfectly understood: and perhaps the difficulties which are supposed to obstruct its more general adoption are overrated. But in every point of view we consider it as a subject well worthy of the attentive consideration of practitioners; and we cannot lay aside our pen without once more recommending it to their most earnest attention.

CONTROVERSY AT ST. GEORGE'S HOSPITAL.

HAVING given insertion last week to the letter signed by three of the physicians and the like number of surgeons of St. George's Hospital, and also to that of Sir Benjamin Brodie, we cannot of course hesitate in admitting the answers of Dr. Wilson and Mr. Walker. We should have limited ourselves to the insertion of their letters, had not the former imputed blame to us for inserting the circular of the physicians and surgeons above mentioned, as well as for expressing the opinion we did upon the subject. The question stands thus:—Dr. Wilson writes as though the physicians and surgeons were the aggressors, and holds that the allegation which they declared to be untrue, had never been made. In approving of the letter, we thought that it had been called forth by an attack upon their colleague and themselves; and on again referring to the newspaper, we still maintain that such was the case; nor are we the only editors who have taken this view*. But that our readers may judge for themselves, we subjoin the paragraph alluded to; and we beg it may be observed, that the types, as to italics, capitals, &c., are copied from the *Morning Chronicle*, without any alteration.

* "During the active canvass, an anonymous notice appears in the *Chronicle*, reflecting discredit on Mr. Brodie and his colleagues."—*Kenshaw's Medical and Surgical Journal*, Nov. 15, p. 506.

Quotation from the attack on Sir B. Brodie in the Morning Chronicle.

"Without making any invidious reflections, we would simply ask whether or not Sir B. Brodie has not been the principal agent and most active canvasser, not only among his brother medical officers, but among the proprietary where he has such personal influence, in persuading them to appoint an *additional* and (if Mr. Walker, whose active and valuable services are acknowledged on all sides, is to be believed) *uncalled for* assistant? and whether or not—and we call upon the governors 'to read, mark, learn, and inwardly digest'—his OWN PRIVATE ASSISTANT (WILSON, in order to avoid the appearance of a JOB, he took special care *not to nominate* HIMSELF), be not one of the candidates? and whose success will be rendered certain, unless the governors shall in this 'eleventh hour' judge for themselves and select Mr. Lane, who has filled all the subordinate situations of dresser, house-surgeon, &c., and who has, from his talents, attention, and consideration to the poor objects under his care, fully entitled himself to be the selected FAVORITE."

Now the above passage (the whole of which is actually one continuous and uninterrupted sentence), is evidently the production of some illiterate person; besides which, we regard Dr. Wilson as too much a man of honour to descend to anonymous slander: for both which reasons we assume that he, like us, can only judge of the writer's meaning by his words.

We submit, that in the above passage the public is given to understand—first, that the appointment of a second assistant-surgeon being "*uncalled for*," was a JOB of Sir Benjamin Brodie's to serve "*his OWN PRIVATE ASSISTANT*;" secondly, that he used his "*personal influence*" with "*his brother medical officers*," in "*persuading them*" to consent to the appointment, notwithstanding that—thirdly, another candidate, Mr. Lane (from certain qualifications which are pointed out), had "*fully entitled himself to be the selected FAVORITE*." Either this is the meaning of the passage, or we profess not to know what the meaning may be. Now even had there been no allusion to the other medical officers, we think that it would nevertheless have been cowardly

and contemptible on their part, not to have stepped forward to support their colleague against so wanton an aggression; besides which, we are still of opinion, notwithstanding Dr. Wilson's letter, that the imputation of being subservient to Sir Benjamin Brodie in the perpetration of a job, and promoting the election of his private assistant because he *was* his private assistant, to the exclusion of a better man, was attributing to them "*dishonourable motives*," and rendered it imperative on them to declare publicly that the imputation was "*absolutely untrue*."

Dr. Wilson informs us that we are "*very partially acquainted with the opinions and feelings of the profession on the subject*." We believe Dr. Wilson to be mistaken in this respect, and that disapprobation not less "*warm and honest*" than that which he has expressed for the letter of his colleagues, has been excited most keenly and generally by the calumnious slander on Sir Benjamin Brodie which called it forth.

We have touched only on the points in which we are ourselves editorially involved, in consequence of Dr. Wilson's observations;—as to the special pleading on other matters contained in his letter, it is for his opponents to deal with it—if they think it worth their while.

We have also to acknowledge the receipt of a note from Mr. Walker, by which we are relieved from much embarrassment. He published a letter in the *Morning Chronicle*, on Friday, the 7th, which was intended as an answer to that of Sir Benjamin Brodie, and which, therefore, it appeared to us that we ought to give in this journal, as we had done the former. But, on the other hand, it contained several things which we feared it might be deemed ill-natured towards the writer to place on permanent record—particularly the avowal contained in the second sentence. The manner, however, in which Mr. Walker appeals to our candour and fairness in the note which accompanies his letter, deprives us of any choice.

P.S.—As this was passing through the press, we received Renshaw's Medical and Surgical Journal. The extract which we subjoin will perhaps tend to convince Dr. Wilson that the current of feeling does not *all* run in the direction he would wish, and that we are not quite so "*partially*" informed as he sup-

poses:—"We think, and we have watched the proceedings at St. George's attentively, that Mr. Brodie has acted with much judgment, and has reflected honour on himself. The motives of Mr. Walker's objection are obvious to every one;—monopoly is an inherent feeling not absent from the breasts of many individuals."

DR. WILSON'S LETTER.

To the Editor of the Medical Gazette.

SIR,

Is a letter addressed by certain Physicians and Surgeons of St. George's Hospital to the Governors of that institution, under the date of November 5, and published by you in the Medical Gazette of this day, there are many confusions of statement and inference, involving me in my character of Physician to the hospital, and which I therefore feel myself called on at once to correct. The letter to which my remarks are directed is in its nature ephemeral,—written and circulated avowedly for an electioneering purpose of the twenty-four hours next ensuing on its publication; and believe me, sir, that I should have left it to the opinion passed upon it in those twenty-four hours, had you not thought fit to keep it before the public for a week beyond the natural term of its existence. Perhaps, sir, I may be thought somewhat over anxious for fame, in directing the attention of your readers to the omission of my own name in the list of physicians to the hospital who have affixed their signatures to this document; but still I think it right thus publicly to inform them, that until I saw the letter in print, I had not the least idea of any such unusual proceeding having been contemplated by my colleagues in charge of the medical business of the hospital. The letter, be it then remembered, sir, was never submitted to me, one of the physicians of the hospital, for approval; it was printed, published, and circulated without my knowledge, and was first put into my hands by a pupil of my anatomical school, grieved and indignant at what, in his warm and honest feeling, he considered to be an unjustifiable attempt to depreciate the professional claims and character of his teacher, Mr. Lane, on the eve of the morrow's ballot. I may here remark, that I have not been even honoured by the presentation-copy of this published letter, which in courtesy should have been transmitted to me as a physician and life-governor of the charity, whose interests, we are advised, would be best served by the election of the candidate therein recommended.

That I should have subscribed to many of the opinions expressed in this letter, my

friends must know to be impossible. I am glad to observe that my colleagues have done me equal justice. Utterly deprecating the principle of combined interference on the part of the medical officers, between the Governors of the hospital and the candidates for their favour,—a principle rendered more obtrusively improper by the time and circumstances under which the letter implying it was written—by the date, and by the place of its publication,—I shall offer no further comment upon its three first paragraphs; they relate to the particular views, considerations, and motives, of particular surgeons and physicians, of which I have no knowledge, and with which I have no right to interfere. I will merely express my honest belief, that in the discussions preceding the appointment of a second assistant surgeon, and in the progress of the canvass for such appointment, there have been about as many unfounded reports, and about as much misrepresentation, on one side as on the other, and that to both a large share of such discredit belongs.

But in the fourth paragraph of the letter your readers will observe, sir, that "the undersigned physicians and surgeons of the hospital" become at once "the physicians and surgeons of the hospital" generally,—not, however, be it understood, by my adhesion to their proceedings; and thus I am obliged to protest against being considered in any way responsible for the opinions which follow. I beg therefore unequivocally to declare, that in my humble opinion, no appointment or right of patronage whatever should be suffered to exist in the establishment of the hospital by its Governors, that can in any way be avoided consistently with the efficient discharge of the medical and other duties of the institution.

It is almost needless to assert, in opposition to what is advanced in the letter of the six physicians and surgeons, that very great personal advantage might occasionally accrue to them, by increasing the number of the officers—an advantage not less than that of securing, under an auspicious election, for a relation or friend, the reversionary share of emoluments, amounting to not less than about two thousand two hundred pounds, annually raised in fees from the pupils in attendance on the medical and surgical practice of the hospital, exclusively of other large sums produced by the several lectures delivered by the medical officers of the hospital.—Certainly, from the appointment of assistant physicians or surgeons, who receive no part of the sums thus annually raised, there can be no possible disadvantage accruing to the full physicians and surgeons of the hospital. On this paragraph, to which in its complete form I beg the at-

tention of your readers, I will further remark, that the appointment of a second assistant-surgeon was not recommended by the physicians and surgeons of the hospital in their collective capacity, which, from the sentence as it stands, the Governors would necessarily be led to believe. The degree of support which this measure received from the physicians of the hospital individually, will be best remembered by those who took part in the oftentimes repeated conversations and discussions on this subject in the board-room of the hospital, five months back. Answering only for myself I can assert, that I was then, as I am now, strongly opposed to the principle of this appointment, and to the way in which it was brought forward, believing it to be unnecessary, and therefore holding it to be improper.

In proceeding with the further examination of the avancements made in the letter of the six physicians and surgeons, you, and your readers, sir, will not be a little surprised to find, in collating this part of the letter with an article in the *Morning Chronicle* of the 4th instant, which it professes to answer, that no such allegations as stated in the letter are actually put forth in that journal. On a moderately attentive perusal of the objectionable article in the *Chronicle*, it will be seen that dishonourable motives are not attributed to the physicians and surgeons of the hospital in their selection of a candidate, and that Sir B. Brodie is not represented to have used undue influence of any kind to induce them to vote for his private assistant; that no imputation attaches to the medical officers which does not attach to what the writer of the paragraph terms "the proprietary;" that "the absolutely untrue allegation" assumed by the six physicians and surgeons in their letter, is more insignificant than even falsehood itself,—that, in truth, it does not exist: to be brief, sir, it is an allegation that was never alleged; and yet, on this "absolute" nothing, an opportunity is constructed for advocating the cause of one candidate, to the prejudice of another. An excuse for this strange oversight on the part of the six combined authors must be found in the haste necessary for the composition, publication, and circulation of the *two* editions of their letter, in the interval of time between Wednesday November 3, and Thursday November 6, on the afternoon of which day it met the country Governors, on their arrival in town for the Friday's ballot. The extent to which correction of the press "has been had recourse" in one edition of the letter, is satisfactory evidence of the extent to which carelessness "had been carried" in the other.

To Mr. Lane's judgment, to his spirit, and self-respect, I leave the task of reply-

ing to the statements respecting his intentions of profit, his calculations of actual profit and loss, in the construction of his anatomical theatre, as an affair of sale and barter. Ample justice has already been done to this part of the letter, by many of the Governors assembled in the board-room on Friday last, in their criticisms of this particular paragraph, inserted, you will observe, between vague charges of slander, and, apropos, of nothing.

I may perhaps here be allowed, as a physician of the hospital, to express my most grateful thanks to Mr. Lane, for having supplied to our hospital school what it most needed, and what no one else could be found to provide for it—a well-constructed anatomical theatre, with dissecting rooms immediately adjoining the walls of the hospital. It is absurd to maintain that any claim preferred to the notice of the Governors by Mr. Lane, or his successors in this school, could supersede their patronage in the appointment of their medical officers, or deprive them of the absolute power to be exercised by their individual votes in the ballot for such appointment. It is well known to each of the six physicians and surgeons who signed the address to the Governors, that a right of control over Mr. Lane's anatomical school has been more than once offered to them, and that, had they been willing to exercise such right, they might long ago have done so.

And now, sir, in reference to the editorial remarks with which you introduce what you are pleased to entitle, "the letter of the physicians and surgeons of the hospital," it is with sincere concern that I am compelled to tell you, that the publication of such letter in your journal will have an effect very different from that of rendering all further allusion to the subject of it unnecessary. Be assured, too, sir, that in the excitement of this canvass, and in the circumstances which led to it, much, very much, has occurred, in addition to the publications to which you allude, which will bring disgust to all honourable and candid minds. And should you really suppose, sir, that irreparable injury is inflicted by these ill-judged publications, on the parties whom, as you assert, they are intended to serve, I will venture in truth and in courtesy to assure you, that you are very partially acquainted with the opinion and feelings of the profession on the subject of this election; and that you greatly overrate the power of the daily and weekly press in these matters; and that you are, moreover, but little acquainted with the firmness of our common English nature. The honest unobtrusive industry of years, the gathered love and respect of friends and pupils—the grateful recollection of

their quick but ready zeal in the struggle just past—will not be at once cancelled by the communication of an anonymous correspondent in a newspaper, of an over-busy friend it might be—it might be of an over-cunning enemy; or even, sir, (and in all good humour be it spoken,) by the leading article of a weekly medical journal.—I am, sir,

Your obedient servant,

JAMES ARTHUR WILSON.

One of the Physician's to St. George's Hospital.

London, Nov. 8, 1834.

To the Governors of St. George's Hospital.

MY LORDS AND GENTLEMEN—In the papers of this day, I have seen a letter from Sir Benjamin Brodie, in answer to some observations which appeared in the *Chronicle* of the 4th instant; and it is quite manifest that the insinuations thrown out by him are intended for no other person than myself. I must, therefore, distinctly deny being the author of that paragraph, though I have no hesitation in stating that I have unreservedly related all the facts connected with the recent proceedings at the hospital to every individual I met with, earnestly hoping that the particulars would find their way into the press, and would lead to the explanation which would now necessarily take place.

This, my Lords and Gentlemen, is what I have earnestly wished for, since a candid hearing has been denied me at the proper tribunal.

Sir Benjamin's statement with respect to the varying number of assistant-surgeons at different periods may, at first sight, appear to carry weight with it; but I trust I shall be able to show that his reasoning is utterly fallacious. At the period to which Sir B. refers, there were no assistant-surgeons to the hospital; individual surgeons who had been many years attached to the institution, it is true, applied for particular persons to be appointed assistants to themselves, and the Governors, not wishing to compel these surgeons to resign, granted the application: thus Mr. Keate was appointed assistant to his uncle; Mr. Brodie to Everard Home; and Mr. Ewbank to Mr. Griffiths; but these gentlemen were never assistant-surgeons to the hospital, though they were unanimously elected surgeons, in rotation, as vacancies occurred in that department. But during the very time that Mr. Brodie was assistant to Sir E. Home, Mr. Gunning being called upon to attend the army as surgeon general in the Peninsula, the patients of Mr. G. were likewise entrusted to Mr. Brodie's care, who attended them

with all the zeal and punctuality which the importance of the charge demanded: thus having under his own care the in and out patients of two surgeons, just half the number admitted on the surgical part of the establishment. This will, I think, show that now an assistant-surgeon is regularly appointed to the hospital, who takes constant charge of the out-patients of the two senior surgeons, and is always ready and anxious to lighten their labours amongst the in-patients, that there can be little real demand for the appointment of a second assistant; for even if the maximum number of beds alluded to by Sir B. be immediately filled, the average division of the surgical patients will not, most assuredly, increase the labour for each surgeon so much as to require an additional assistant.

I will not now dwell on the former custom of appointing private assistants: it is well known to many Governors, and was found so highly objectionable on many accounts, that it was deemed advisable to add one assistant to the regular hospital staff. I am grieved to see a gentleman, holding the elevated position in society which Sir Benjamin does, coming forward to give currency to an assertion which he must, if he has an honest memory, know to be incorrect. I did not object to the appointment, upon grounds which he states, a monopoly only; and it must be manifest to the Governors that such a request coming from the surgeons, and that without my being made acquainted with their intentions, becomes at once a question of character; and the apparent natural inference which strangers would draw, would be the inefficient performance of the duties by the present assistant. In fact, Sir B. did insinuate something of this kind, but I challenged inquiry, and these insinuations were withdrawn, and a most satisfactory Resolution as to my conduct carried unanimously at the Board, on the 1st of July, and entered on the minutes of the Hospital. I feel called upon to give this hasty but immediate reply, as the letter from Sir B., while most unjust and unfair towards myself, is calculated to be of serious injury to my friend Mr. Lane, whose high qualifications as to moral worth and professional character are before the Governors, and I have confident hope that they will give him their utmost support.

I have the honour to be,

My Lords and Gentlemen,

Your most obedient humble servant,

R. B. WALKER,

Assistant-Surgeon to St. George's Hospital.

27, Curzon-Street, Mayfair.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY;

LATE

MEDICO-CHIRURGICAL SOCIETY.

Tuesday, Nov. 11, 1834.

The New Charter.

THE Fellows of this society held their first meeting for the present session, on Tuesday evening last, at the house of the President. The meeting was numerously attended; none of the ordinary business of the society was transacted, the time of the Fellows having been exclusively occupied in discussing questions arising out of the grant of a charter of incorporation, just received from the Home-office. After taking the chair, the President proceeded to read the charter, which ran in pretty nearly the terms usual, so far as we know, in such cases—viz. His Majesty declares himself patron of the society, willing, that the members shall be entitled "*Fellows*;" the incorporation be styled "*The Royal Medical and Chirurgical Society of London*;" the incorporation be qualified to plead and be impleaded; be entitled to hold property to a certain amount; consist of a council and fellowship, &c. &c. It contains, also, several other provisions, which appeared to us to be borrowed from the old statutes, of which, in fact, the instrument seemed in the main a summary or abridgment, leaving, however, abundant discretionary power, as to details or *by-law* (the charter term) legislation, in the hands of the society. The only names mentioned in the instrument are those of the President (Dr. Elliotson), Sir Astley P. Cooper, and Dr. Yelloly—the two latter distinguished gentlemen being the survivors of the original petitioners, in conjunction with the late Dr. Mareet. After the charter was read, many gentlemen offered suggestions; but in consideration of the novelty of the society's position, and the importance of the first proceedings in a legal point of view, it was resolved at length that a general meeting should be held that day fortnight for finally determining what should be done, and that meanwhile the charter should be printed and put in circulation among the Fellows; and the meeting adjourned, without having taken any final step, except voting an humble address of thanks to the King for his gracious patronage and royal charter.

The meetings, we understand, are to be held at the house of the President, until the society's apartments in Berners-street are quite ready for occupation. We are

informed, that should time permit, there will be read on the next occasion, viz. the fourth Tuesday of the month, a paper by Dr. Wilson Philip.

GLASGOW EYE INFIRMARY.

CASE I.—*Crystallino-Capsulitis*.

ROBERT DUNN, a seaman, aged 38, admitted by Dr. Mac Kenzie, 18th Sept. 1834.

The left pupil is somewhat less than the right, of an egg-shape, and moves little on exposure to different degrees of light. When the eye is viewed through a magnifying glass of an inch focus, an infinite congeries of red vessels is seen within the verge of the pupil, on the lower outer part of the anterior hemisphere of the crystalline capsule. He says the vision of the left eye has been dim for seven years; at which time he was affected with severe pain in the eye and head. About three weeks ago he had another attack of redness and pain of that eye, since when he has been affected with a feeling of stiffness in moving it from side to side, and an additional dimness of sight. He attributes the last attack to cold.

Venesectio.—Belladonna ad palpebras sinistras.

R Submur. Hydr. gr. vj. Opii, gr. j. M. ft. pulvis, h. s. sumendus. Cras mane capiat Sulph. Magn. ʒj.

19th.—Blood not buffy; feels his eye less stiff; pupil very little dilated.

Capiat Pil. ex Submur. Hydr. gr. ij. et Opii, gr. ss. ter in die.

21st.—Complains of circum-orbital pain. Cueurbitula cruenta ad tempus sinistram.

22d.—No pain since the cupping. Red vessels in capsule do not appear so much aggravated. Vision clear.

25th.—Pupil considerably dilated; some slight adhesion of the outer lower edge of the pupil to the crystalline capsules; vision much improved; red vessels in capsule much shrunk.

27th.—Mouth pretty sore.

Omittantur pilulæ.

CASE II.—*Crystallino-Capsulitis*.

John McKenzie, a worker in a foundry, aged 16, admitted by Dr. Mac Kenzie, 18th October, 1834.

Right eye pretty natural, and its vision good. Thinks he never saw perfectly with his left eye, but at no time has it been affected with any considerable pain. Has often had fires on his eyes, and there is a

small particle of cast iron imbedded beneath the conjunctiva on temporal side of right eye, which gives him no uneasiness. The left pupil is less than the right, and the left iris a little different in colour from the right, and somewhat dull in its appearance. The left pupil is irregular in shape, but its motions are lively and extensive. On concentrating the light with a large lens upon the left eye, the anterior hemisphere of the crystalline capsule seems slightly opaque; but on looking at it through a lens of short focus, it is seen to be covered with innumerable red vessels, which are spread pretty equally over the whole of it. At the upper-outer edge of the pupil there is a small swelling of the iris. The pigmentum nigrum within the verge of the right pupil, presents its natural appearance and deep-brown colour, when viewed through the lens; but round the verge of the left, it is not so distinctly seen. Vision of left eye is so dim that he does not see the letters on the Infirmary card, while with the right eye he reads it easily. Tongue foul; pulse 72.

Venesectio.—Capiat Pil. Submur. Hydr. gr. ij. et Opii, gr. $\frac{1}{4}$, ter in die. Belladonna ad palpebras sinistras.

19th.—Blood not buffy. Pupil scarcely dilated.

Vesicatorium pone aurem sinistram.

22d.—Thinks vision of left eye somewhat clearer.

Capiat Olei Ricini, \mathfrak{z} j. Instillatur in oculum sinistrum gtt. solutionis aqueosæ Belladonnæ.

27th.—Mouth sore.

Omittantur pilulæ.

29th.—Left pupil somewhat dilated, the aqueous solution of belladonna having been applied once a-day. Red vessels in capsule are evidently somewhat shrunk, and are more scattered than at his admission. Vision continues to improve.

Cases of crystalline-capsulitis are probably not unfrequent, but, as they present only very slight symptoms to the naked eye, are very apt to escape detection. This disease is, no doubt, the foundation of many capsulo-lenticular cataracts.

GUY'S HOSPITAL.

Operation for Strangulated Femoral Hernia.

As Irishwoman, æt. 66, was admitted into Esther Ward on Friday last, under the care of Mr. Key, with strangulated femoral hernia of the left side, which had ex-

isted five days. Considerable tenderness was present over the abdomen when slight pressure was made. There was great anxiety of countenance, and her features made her appear more aged than she really is. Her strength was considerable. All the usual symptoms of strangulated hernia were present.

Mr. Key determined upon operating immediately. The woman was brought into the theatre at eight o'clock p.m., when Mr. Key commenced by making an incision across the tumor parallel with Poupart's ligament; another incision at right angles with this, was carried directly upwards from its centre, thus forming the letter T inverted. The flaps were dissected back, and the true coverings exposed. The peculiar fecal, or gangrenous odour, was now evident through these tunics. Mr. Key now divided the fascia propria (consisting of the cribriform fascia, the anterior portion of the femoral sheath, and the crural septum) upon the director. The sac thus exposed was then opened, and the intestine, which was merely a small knuckle, was found in a sphacelating condition.

The stricture existed at the usual place, namely at Poupart's ligament, and was readily relieved by dividing some few of its inferior fibres. The gangrenous portion of the intestine was then opened, and brought in apposition with the external wound, so as to form an artificial anus; the patient was then removed to bed, and brandy with laudanum ordered to be administered during the night.

At the conclusion of the operation, before the pupils left the theatre, Mr. Key made a few remarks relative to the operation. It is to be hoped that this example will be followed by the other surgeons, and that practical remarks be made at the time, and upon the spot; for it is undoubtedly the most effectual mode of conveying information.

On the following morning the patient's pulse was found still to be good, though her countenance was expressive of the greatest distress. The feces had passed by the wound. She had dozed a little during the night. Four or six ounces of brandy, with a drachm of laudanum, had been given at intervals during the night and fore part of the morning. The brandy was ordered to be continued.

Sunday morning.—She has passed a better night, but still has tenderness over the abdomen. The pulse is tolerably good. Her feces pass freely from the wound, but none pass per anum. Her powers are greater than could have been expected. Complaints of sickness, which she says is checked by taking the brandy.

Monday morning.—Has little or no ten-

derness over the abdomen; was very restless during the night, having had very little sleep. Her pulse is still tolerably full, and of moderate power. Has hic-cough, which is not constant, but is present for a short time, and then leaves her. The fascial coverings to the hernia, which were divided, have sloughed for a short distance around the wound, and were removed by Mr. Key with a pair of dressing forceps. The wound is looking healthy, and the faeces have a ready passage through it. The woman appears to be suffering simply from want of power. Mr. Key ordered her a table spoonful of brandy every hour. Porter, which she expresses a great wish for, is allowed *ad libitum*. Mr. Key has likewise prescribed—

Infus. Serpentariae, ℥iss.; Tr. Card. C. ʒij. to be given every sixth hour.

Tuesday morning.—Is in every respect much the same as yesterday.

The patient gradually sunk, and expired early on Thursday morning.

Fracture of the Ilium, with Dislocation and Rupture of the Ligaments of the Knee.

Several severe accidents have been admitted into this hospital during the last week. One case more particularly worthy of notice was brought in on Thursday evening, where the ilium was fractured below the anterior superior spinous process, with dislocation at the sacro iliac synchondrosis. The knee was likewise dislocated, all the ligaments having been ruptured except the ligamentum patellae. The man, who is about 30 years of age, has great power, for the constitutional excitement which is induced is not near so considerable as might have been expected. Sir Astley Cooper has seen the case, and his prognosis is favourable. The leg is placed on a double inclined plane, with lateral splints to give support to the knee; the pelvis has a bandage passed around, to give it support.

The man possesses power to retain and expel his urine and faeces. It is rather singular that so serious an accident could have occurred without materially injuring either of the important organs contained within the pelvic cavity.

A PUPIL.

ST. GEORGE'S HOSPITAL*.

Acute Hysteria, simulating Peritonitis.

HARRIET CANNING, æt. 17, admitted August 6th, under the care of Dr. Macleod.

* The cases in the No. for Nov. 1st, page 173, were treated by Dr. Seymour.

Complains of very acute pain in the right iliac region, extending towards the umbilicus. The slightest touch, when her attention is directed to the part, excites the most exquisite pain; but if the attention be diverted, firmer pressure is borne with scarcely a consciousness of the contact. Pulse variable, but the prevailing character is that of frequency, with softness. Tongue whitish, moist; bowels regular; general appearance delicate.

The pain came on a week ago, and has continued unmitigated up to the present time. Catamenia appeared about the same period, after an absence of many weeks.

R Pil. Galban. Co. gr. v. fiat Pilula, ter die sumenda.

R As. ætoid. Gum. ʒss. Aquæ Tepidæ, ʒvj. M. fiat enema vespere injiciendum.

8th.—The pain was so much relieved, that pressure could be borne yesterday under any circumstances, without complaint; to-day, however, there is some return of the pain, in the same spot as before. Bowels rather confined.

Pil. Aloes et Assafoetid. gr. v. ter die. Decoct. Aloes Co. ʒiss. eras mane. Empl. Belladon. c. Camphora*, parti abdominis dolenti.

14th.—Free from pain; bowels open; tongue clean.

Perstet.

16th.—Bowels very much purged; pain a little below the right mamma, increased by pressure, or deep inspiration; some return of the pain formerly complained of in abdomen; headache; tongue disposed to become furred; skin cool; pulse natural.

R Mist. Cretæ; Infus. Catechu, aa. ʒiij. Tr. Opii, ʒss. M.—sumantur Coch. Magn. ij. post singulas dejectiones liquidas.

[Diarrhœa was at this time very prevalent in the hospital.]

17th.—Purging stopped.

R Træ. Valerian. Ammon. ʒj. Aquæ Menth. Pip. ʒxi. M. ft. haust. t. d. s. Omittantur alia.

19th.—Quite well.

She was discharged in a few days afterwards, free from complaint.

REMARKS.—The striking features of this case were the aggravation of the pain on pressure, to an extent bearing no proportion to the force employed, and the im-

* The plaster used by Dr. Macleod, under the above designation, is composed of equal parts of extract of belladonna, emplast. saponis, and camphor: care being taken that the heat of the spatula be not so great as to dissipate this last ingredient.

mediate reduction of this exalted sensibility to the natural standard, or at least the temporary cessation of the symptom, by engaging the attention with something alien to the complaint. No symptoms more clearly distinguish between inflammatory and nervous disorders than these. In inflammation, the pain produced by pressure bears a relation to the force employed, nor does mental abstraction, unless very profound, enable the patient to endure external impressions without being instantly awakened to their presence. Yet it is astonishing how many cases of nervous disorder are brought to this hospital, wherein, prior to admission, an erroneous diagnosis having been made, a plan of treatment has been pursued calculated rather to perpetuate than remove the disorder. A girl complains of acute pain in the right hypochondrium, for example, aggravated by pressure or deep inspiration, and, forthwith, severe depleting measures are had recourse to, because this symptom happens to stand in the list of those indicative of inflammatory action. I have known it occur more than once, that, on being interrogated as to her complaint, a patient has replied, "I have got an inflammation of my liver; the medical gentleman who has attended me, told me so. I have been bled for it, and have had leeches applied, but am no better than before."

It is from directing the attention to one symptom alone—the most prominent it may be—that such errors arise; but if, on the contrary, we connect carefully all that present themselves—the negative as well as the positive—there will occur but few instances in which doubt can exist. The case above-related is one of frequent occurrence, and very fitted to illustrate my remarks. There was severe pain under the circumstances pointed out, but with this there was no hardness of the pulse, no coating of the tongue, no dryness of the skin, no thirst—no symptom, in short, indicative of the febrile excitement that marks the existence of inflammation; and though the report of the 16th would seem to indicate a relapse into a condition, worse even than that originally complained of, this arose, manifestly, from the debilitating effects of the accidental diarrhoea. The great majority of hysterical patients do not bear reducing measures: attention to the bowels, with the employment of the diffusible stimuli and the foetid drugs, I have known, again and again, to remove quickly the most severe pain, though it may have lasted for weeks, and have defied the most active depleting treatment. The application of the belladonna and camphor plaster, in the case of Can-

ning, brought relief after the lapse of a few hours only; and this likewise is an effect I have witnessed many times in the wards of St. George's Hospital.

The clinical books of the physicians abound in cases of hysterical disorder, for which the sufferers have applied for hospital relief, as a sort of last resource, and of which they have there been cured in the short space of a week or ten days.

Amenorrhœa speedily cured by Leeches to the Groins.

September 3d, Mary Moulton, æt. 16, admitted under the care of Dr. Macleod. Complains of pain a little beneath the right mamma, extending across the chest towards the left side; not increased by deep inspiration, and unattended with cough. Has frequent nausea, and vomited a small quantity of blood a few days ago. Bowels habitually costive; pulse 100; skin hot; catamenia absent four months.

Applicetur Hirud. xij. inguinibus.

R Pil. Aloes et Assafetid. gr. x. omni nocte. Utatur Balneo Coxario, alterna quaque nocte.

5th.—Catamenia appeared, though rather scantily, immediately after the leeching. Pain in the chest relieved; bowels open; pulse and skin natural.

Repetantur Pilulæ.

13th.—Has occasional flying pains about the chest, but her general feelings are very much improved.

Pil. Galban. Co. gr. v. t. d. Decoct. Aloes. Comp. ʒiiss. alt. auroris.

19th.—Discharged cured.

REMARKS.—It does not often happen that the menstrual discharge is made to flow by the application of a few leeches to parts in the neighbourhood of the organ supplying that secretion: it is for the purpose of adding one to the scanty list of such successful cases that I am induced to record the foregoing example; but I am inclined to believe that the infrequency of the occurrence arises, in a great measure, from two circumstances—viz. an injudicious selection of the cases for which the remedy is adopted, and its ill-timed application. It would be absurd, of course, to have recourse to local depletion in a patient whose disorder was connected with a languid condition of the general circulation; but the case before us was one indicative of sufficient constitutional power, though restrained by some local derangement of function. The accustomed period had arrived, and symptoms existed which seemed to shew that nature was

making an effort to establish regularity of action in the peccant organ. There were a quick pulse, and a hot skin. The physician, therefore, perceiving the opportunity, supplied the little assistance that nature required, and at the very moment she needed it.

Perhaps the discharge of blood from the stomach may have been an attempt, on the part of the constitution, to effect vicarious menstruation: at all events, it is well known that vomiting of blood is more common during retention of the menses than at any other time.

A PUPIL.

MIDDLESEX HOSPITAL.

CASE OF PERICARDITIS; WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

I AM desirous of presenting to your readers a case of pericarditis, unusually interesting, now under treatment in this hospital.

I am, sir,

Your obedient servant,

G. C.*

Middlesex Hospital,
Oct. 29, 1834.

It is a painful circumstance to witness the servile attention and regard that medical pupils pay to such works as Thomas's *Practice of Physic*, and other elementary works in this department; but equally painful is it to see them guided by the opinions their authors adopt: one elementary work especially discourages young men from studying auscultation at all, and the author's pretext is readily seized as a good excuse for not devoting a few months' assiduity to a course of study which will ever prove of inestimable value to both practitioner and patient; at least it will save the former from a painful reflection, which he must one day suffer, that he has not used to the best advantage those instruments of acquiring knowledge which were within his reach during his pupillage at a large metropolitan hospital.

I am induced to offer these remarks, from a conviction that the valuable pathological Essays on Diseases of the Heart, by Dr. Latham, published in vol. iii. of *Medical Gazette*, and Dr. Hope's admirable work, are not duly appreciated and read by the student in medicine. They present to us compositions of the highest character: the one for the discovery of an

unerring guide in the diagnosis of acute inflammation of the pericardium, and the great practical lesson to be reaped from it; the other equally valuable for its explanation of the physical signs of the heart's action in health and disease.

In Dr. Latham's fifth essay it is stated, that the most useful accession to diagnosis that auscultation has afforded, exists in the establishment of the fact, that "a morbid sound with the heart's action invariably is present in acute inflammation of the pericardium." I may safely say, that in one hundred cases I have witnessed during the last four years, I have not seen cause to doubt the fact in any; and the truth of it has been pronounced sooner or later by the progressive alteration and subsequent distress in the functions of the heart and lungs, and by dissection.

A case similar to the subjoined was related by Dr. Watson, in his clinical lectures, published last year in the *Medical Gazette*. The present one is that of a servant, 22 years of age, admitted under Dr. Wilson, October 21, with rheumatism, of a fibrous form, ten days standing. The patient's countenance was profusely perspiring, and her features continually in a "broad grin." Excepting a sense of weight at the epigastrium, she presented no symptoms of internal inconvenience; the pulse was 110; respirations frequently sighing; and on applying the stethoscope over the region of the heart, there was distinctly heard a morbid sound accompanying, both systole and diastole; with the former it was harsh, grating, and close to the ear; with the latter it was a deep churning sound. The systolic rough sound was only heard over the space of a crown-piece, about an inch from the sternum; the diastolic "souffle" was detected in every part of the præcordial region. Previous cases had taught in too melancholy a language the importance of vigilant treatment being instantly adopted; she was accordingly bled to xxxvi. , but syncope could not be induced. Hirudines xx. applied to the præcordia, and the following pill every four hours:—

Pil. Hydrarg. gr. iv.; Hydr. Submur.
gr. ij.; Opii. Pulv. $\frac{1}{4}$ gr.

The deep diastolic sound only could be heard after the venesection.

In the evening the two sounds returned as distinctly as before the venesection, but lessened in intensity.

Ung. Hyd. Fort. 3j. cruribus infricandum nocte manequæ. P. Pil.

Oct. 22d.—Was found to have passed a quiet undisturbed night; is perfectly collected, and not complaining of any pain

* The name has been sent to us.—ED. GAZ.

internally; the rheumatic pains better. The sounds are now as loud as yesterday before the depletions, the pulse 100, and the sense of weight at the epigastrium gone.

Rep. V.S. ad ξ xvii.; adde Pilulis singulis Antim. Tart. $\frac{1}{2}$ gr.

The sounds altered after the venesection as yesterday, but became faintly audible towards the evening.

23d.—She has passed another good night, and the features are assuming a more natural aspect. The systolic *bruit* audible in a slight degree; the “*souffle*” is very loud.

P. Pil. et Ung. Hyd.

24th.—No effect has hitherto been produced on the gums by the mercury. The first sound is now more allied to a carpenter's plane, and is as it were close to the skin.

28th.—She is now affected by the mercury, and there is purging. The rheumatism is well. She is free from pain, and makes no complaint. Is anxious to leave her bed, but that is not yet permitted. The sounds are strictly the same as on the 23d, but appear to get fainter daily, especially the systolic grating. Is this produced by attrition of lymph exterior to the heart? or is it within the organ?

On the day that the above case was admitted, a post-mortem examination was made of a child 10 years old, who had been confined to her bed sixteen months previously with acute rheumatism, attended with violent delirium. As this latter symptom subsided, the child became greatly distressed in her breathing, and had palpitation of the heart, with some cough. For these she was admitted in the spring of 1833, under Dr. Watson, and quitted the hospital in December last, very little benefitted. The heart's action during the whole period was attended by a loud “churning” noise.

She returned on the 21st of this month, and sought admission into the hospital. In the course of the day, as she was attempting to get from her bed to the chair, she suddenly expired.

The heart was equal in size to that of a full-grown person. Some bands of adhesion were seen between the pericardium and heart, and mamillated points projected from the surfaces of the auricles.—Along the edges of the tricuspid and mitral valves were seen numerous seed-like deposits.

That portion of the internal lining of the left ventricle, before the aortic valves, was thick, and appeared like washed leather for the space of an inch.

This morbid condition of the membrane

had so contracted and bound down the aortic valves to it, as to render them perfectly useless. The mitral valve was as thick as a half crown piece. There was a large portion of the lung in a state of pulmonary apoplexy.

SURGICAL REPORTS

FROM THE

LONDON DISPENSARY.

By R. R. ROBINSON, Esq.

Surgeon to that Institution.

CASE I.—*Extensive Malignant Ulceration of the left side of the Face — Enlargement and Induration of the Cervical Glands.*

WILLIAM ELLIOT, *æt.* 50, admitted April 16th. About four years ago he perceived a small swelling under the lower palpebra of the left eye, like a wart, which increased gradually in size. He went into an hospital, where remedies were used to destroy the surrounding skin: he left it two years ago, since which the disease has considerably extended. The left side of the face is now completely gone; in its room is an ulcer, with healthy granulations, extending from the ear (which is included) down to the symphysis of the inferior maxilla. The edges, however, are hard and puckered; the inferior part of the left orbit is quite destroyed, as are also the left malar and superior maxillary bones, except two small portions which stand out from this immense excavation in a state of necrosis, discharging a healthy-looking but offensive pus, tinged occasionally with blood. The left eye is reduced to a round tense ball, very tender to the touch; the cornea completely opaque. He experiences excruciating pain in the wound, from which saliva is constantly dribbling. The mouth can only be opened to a very small extent, and he has difficulty in swallowing. About the middle of the neck, on the left side, there is a cluster of glands about as large again as a nut, exceedingly hard, and firmly adherent to the skin above, and to the superficial fascia below. Much emaciated; bowels open.

Pulv. Doveri, gr. x. n. et m. Cat. Panis.

July 9th.—Pain most excruciating; cannot obtain rest even with opiates; the remaining portions of the malar and superior maxillary bones have exfoliated and come away entirely; the bones of the orbit are also more exposed and necrosed, but the granulations throughout the whole wound are very healthy; the ulceration

extends down the neck. Below the ear there is another indurated gland; those lower in the neck larger and still harder than they were.

Rep. Opium.

August 9th.—The ulceration extended deeper, and his pain continued excruciating, until released by death this day. A slight bleeding occurred now and then, but not to any amount. I had not an opportunity of examining the body.

REMARKS.—This case affords a good illustration of the great ravages that may follow a simple pimple of the skin. I believe this disease commenced in the glandular substance of the cutis vera; that it spread by ulceration from one follicle to another, until a considerable extent of skin was implicated; the parts beneath then became affected, the eye was inflamed and destroyed, the bones also of the cheek became involved, and the irritation was propagated to the cervical glands, in consequence of which they became enlarged, adherent, and decidedly scirrhus. The progress of the disease was exceedingly slow, but the pain very severe. No benefit appears to have resulted from escharotics, which were applied at its commencement. The disfigurement of the face was frightful, and such as I never witnessed but in one other case, where both sides of the face were very considerably destroyed, and the mouth and nostrils laid into one large irregular cavity, by an ulceration of similar character. This man appeared to die exhausted by long-continued suffering, though it is not improbable that the ulceration might have extended towards the base of the brain, of which, however, there were no symptoms. I much regret I could not clear up this point by dissection.

CASE II.—*Malignant Ulceration of the Mouth*
—*Hydrocephalus*

John Andrews, *æt.* 65, admitted December 28th. Perceived a small pimple on the inside of the right cheek some time ago, which ulcerated, spread slowly, and was attended with a shooting pain. The ulceration has now extended throughout the interior of this cheek, giving it a puckered, hardened, granular appearance; it is covered at parts by altered cuticle, and discharges an offensive saliva; the ulceration now extends towards the tonsil. For the last three months he has been unable to open his mouth above an inch. The submaxillary gland on this side was much indurated, but has in the last ten days softened; and now there is here an evident abscess, excessively tender to the touch, but which he will not allow to be opened. He can only swallow liquids; is much

emaciated; nights generally restless; countenance leaden, almost livid; headache, dyspnoea, and cough, to which he is subject every winter; respiration at parts dull, rhonchus mucosus at others. Pulse regular; bowels open.

Cat. Panis. Ext. Conii, gr. viij.; Cal. gr. j. o. n.

Jan. 6th.—The abscess under the chin broke this morning, and discharged much healthy-looking pus; freer from cough; weaker.

11th.—More pain in the mouth; ulcer extends backwards; bleeds slightly at times; abscess still discharges, though less freely; cough gone.

18th.—Continued much in the same state, and died yesterday.

Dissection.—Dura mater firmly adherent to the arachnoid in the whole course of the longitudinal sinus. Arachnoid and pia mater preternaturally vascular, thickened, and gelatinous. A considerable quantity of serous fluid, tinged with blood, in the ventricles on the surface, and in the base of the skull, amounting altogether to 5viij. Upper surface of the brain healthy; in the vicinity of the thalami (posteriorly) in a state of ramollissement; the base of the brain and nerves healthy. The ulcer occupied the whole of the right cheek, had destroyed the right palate bone, and part of the right ramus of the inferior maxilla. Towards the pharynx the mucous membrane was of a black colour, to the extent of a shilling, and rather hard. Pharynx itself, as also larynx, healthy.

Cartilages of the ribs ossified. Lungs slightly adherent to the chest; left in a state of engorgement, and easily lacerable; right also engorged. Coronary arteries ossified; mitral valves a little thick, not bony. Slight hypertrophy of the left ventricle; ossific spots in the aorta. Abdominal viscera healthy, with the exception of slight thickening about the pylorus.

REMARKS.—The ulceration in this case appears to have been of the same character as in the preceding; it commenced, however, on the inside instead of the outside of the cheek,—in the salivary glands, perhaps,—instead of in the follicles of the cutis vera. As the right palate bone was destroyed by the disease, it is not improbable that the serous effusion within the cranium, the vascularity, thickening, and gelatinous appearance of the arachnoid and pia mater, resulted from propagated irritation, and were consequently secondary to the ulceration of the cheek. It is curious that effusion to the amount of eight ounces should have taken place within the cranium, and not have been manifested

during life by convulsions, coma, delirium, or any symptoms of cerebral disturbance; which I would explain either by supposing that the fluid was very slowly effused, as in chronic hydrocephalus, or that a great part of the serum exuded from the vessels *in articulo mortis*, or even *post mortem*. The state of the lung appears to have existed during life, and may be accounted for, perhaps, by the irritation evidently going on in the system, and by the congestion which must necessarily have arisen from the thickening of the mitral valves, and other disease of the heart.

ACCOUCHEURS AND NURSES— POUNDAGE SYSTEM.

To the Editor of the Medical Gazette.

SIR,

As your pages have ever been open for the exposure of real abuses in the profession, I take the liberty of handing you the following fact. Perhaps you may be as ignorant as I was a short time ago, of a practice pursued by some medical men in the city, which I hope, for the honour of the profession, is not very general—namely, the practice of paying over a portion of the fees received by them as medical attendants at an accouchment to the nurse, which portion receives the name of *poundage*. Now, sir, as it is not common for any one to give up what he is justly entitled to without some return, I fear such conduct will raise a suspicion that the individuals concerned are not the most immaculate. To say the least of it, such a proceeding is highly culpable, as it must injure the respectability of the profession. A farther explanation might be given, but I hope this hint may be sufficient for those pursuing this course, and for preventing others from following their example, as also to remind them, that if they do not respect themselves as they ought, they at least should not lessen the respectability of their brethren in the eyes of the public.

I am, sir,

Your obedient servant,

EDWARD DUNCAN.

3, Leadenhall-Street,
Nov. 11, 1834.

OPERATIONS AT GUY'S.

To the Editor of the Medical Gazette.

SIR,

I SEE in a preceding number of your journal some remarks made on the operating theatre at Guy's Hospital; but as the building of a new theatre would require some little time to accomplish, allow me to throw out a few hints respecting the

present. And first, I would say that, generally speaking, there is sufficient room for the average number of students who usually attend, provided they had the full benefit of the places they take; this, however, is far from being the case; for instead of the operating and assistant surgeons and dressers for the week (who certainly are all required in any operation) being within the circle allotted to them, there are besides, visitors, demonstrators, dressers, and ex-dressers, crowding in around the patient; and they, together with those immediately behind, being obliged to reach over to obtain a sight, wholly exclude the benefit of the operation from those pupils who are less fortunately situated. It is but justice to Mr. Browell to say, he has once *spoken* of it, but he will only be *doing* justice to the pupils by enforcing it; although I trust the persons alluded to will absent themselves of their own accord, and thus give the student the advantage of the money paid for witnessing surgical operations, and at the same time prevent those inhuman cries of *heads, heads, dressers' heads*, which every now and then burst forth from every part of the theatre, whilst the patient is writhing beneath the torture of the scalpel. I wish to know my profession, and therefore require the advantages above alluded to.

A GUY'S PUPIL.

Nov. 10, 1834.

MEMOIR ON THE LYMPHATICS OF THE SKIN, OF THE SEROUS MEMBRANES, AND OF THE NER- VOUS AND MUSCULAR TISSUE.

BY V. FOHMANN,

Professor at the University at Liege.

THIS author has placed himself in the first rank among the anatomists, by his work on the communication of the lymphatics with the veins, in 1821; his beautiful anatomy of the lymphatics of fishes, in 1825; his work on the lymphatics of the placenta, and umbilical cord, in 1832, and which forms the first part of the present series. M. Fohmann far outstrips his rival, Mascagni, not only in ascertaining the disposal of the lymphatic trunks, but in his search after the distribution of these vessels in the very tissue of organs; which, as Mascagni observes, is the most important point to be sought after.

The ultimate distribution of lymphatics is admitted to vary in each organ; the same observation is to be made on the blood-vessels. M. Fohmann shews that the lymphatics do not arise for the most part by free radicals, but by anastomosing plexuses, deprived of valves, and which are finer and nearer to each

other, the closer they are placed to the free surface of the tegumentary, serous, and mucous membranes. There cannot, then, be open orifices at the extremities of vessels; these organic orifices, if they did exist, could only be found in the coats of the vessels.

The first plate of the work represents the lymphatics of the integuments of the chest; the second, those of the serotum, the skin of the penis, and glans; third, those of the mucous membrane of the œsophagus and stomach; fourth, the lymphatics of the mucous membrane of the ileum; fifth, those of the mucous membrane of the colon; sixth, lymphatics of the mucous membrane of the tongue, larynx, trachea, and bronchi; seventh, those of the urinary bladder and urethra; in the eighth are represented the lymphatics of the serous covering of the heart; in the ninth, those of the pleura covering the diaphragm, and those which form (*gaines*) meshes around the fibres of this muscle; in the tenth plate are represented the lymphatics of the arachnoid and pia mater: those plates are all very carefully engraved.

This work is additionally useful to anatomists, as it gives the manipulations of those materials by which M. Fohmann has been enabled to make his preparations; and we may be assured of the accuracy of the plates from this circumstance, that M. Lauth has succeeded, by following his directions, in injecting several parts which have afterwards exactly corresponded with the delineations of M. Fohmann.—*Dublin Journal*.

MUNIFICENT DONATION.

A PARISIAN lady, of distinguished personal and mental accomplishments, died lately, in consequence, it is said, of a shock which preyed on her health for the last two or three months. After bequeathing a number of legacies to various persons, she leaves an annual prize of 5000 fr. to the Académie de Médecine, to be given to the author of the best work on the prevention, alleviation, or cure, of bodily disorders, proceeding from mental anguish. Madame Recamier, who is the executress, had the announcement made to the Academy through M. Bourdois de Lamothie.—*Gazette des Hôpitaux*.

SYMMETRICAL DIVISION OF THE HEART.

M. CRUVEILHIER lately presented to the Anatomical Society of Paris a heart which he had been able to separate into two symmetrical and equal portions, in the manner which had been previously done with respect to some of the lower animals.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES ON THURSDAY, NOV. 13, 1834.

Thomas Middleton, Manchester.
William John Harris, Manchester.
Frederick Palmer, Great Yarmouth.
Frederick Yate, Madeley.
Thomas Moore Parke, Askrigg, Yorkshire.
Theodore Dennis, Winchester.
George Seymour Dixon, Wolsingham, Durham.
John Henry Simpson, Loughborough.
Edward Tweddle Atkinson, Richmond, Yorkshire.
William Abraham Cox, Somersetshire.

IN THE PRESS.—M. Louis's Work on Phthisis; translated from the French. With Introduction, Notes, and Additions, by Charles Cowan, M.D.E. M.D.P. &c.

LECTURE VIII.

DISEASES OF THE AERIAN PASSAGES.

PITUITOUS CATARRH.

WE have occupied so much time in the description of the acute and chronic forms of mucous catarrh, that we shall have less occasion to dwell on the other species, as they all bear a great affinity to each other in their morbid anatomy, signs, and treatment.

You recollect, gentlemen, the difference between mucous and pituitous catarrhs. Mucous catarrh is an inflammation of the aerian mucous membrane, having for its result a secretion of a *yellow* matter; in pituitous catarrh the secretion is *transparent, colourless, and viscid*. Pituitous catarrh, like the mucous, is divided into acute and chronic varieties, and we shall commence with the acute form.

ACUTE PITUITOUS CATARRH.

Morbid Anatomy.—The aerian mucous membrane is moderately swollen, and frequently somewhat softened; it is rarely extensively reddened, but generally spotted irregularly. You will also find, that, in almost all severe cases, the air-cells of the lungs are more or less infiltrated with serum.

The membrane is in the first instance dry; soon, however, the same sort of acrid,

thin, and colourless secretion takes place, as I described in the acute mucous form, and the fluid then becomes bland, viscid, without colour, and transparent; it has a certain degree of tenacity, so that it may be drawn out into long films. The expectorated matter, when collected in quantities, is spumous; and when its surface is removed, the fluid beneath appears like a mixture of white of egg and water. The quantity varies, but it is generally considerable.

Local Signs.—The respiratory murmur is less audible during the accesses of cough than in the intervals between, but it is rarely completely suspended, as in acute mucous catarrh—the sonorous wheezing, sibilation, and the mucous rattle, may all be heard upon an extent of the surface of the chest, proportionate to the bronchial tubes affected. The sibilation is often slight, and seems to be prolonged in the whole of the bronchi: Laennec denominates this the *sub-sibilant respiration*. The respiratory murmur is often louder than natural during the intervals of coughing, so as to be nearly puerile. If the bronchial tubes be dilated, it becomes bronchial; and as the disease is frequently accompanied by serous effusion into the air-cells, the crepitating rhonchus is then distinctly audible, particularly at the parts of the chest corresponding to the lower and posterior portions of the lungs.

Functional and general Signs.—This disease is not uncommon in a moderate form, but there is then always a troublesome cough, occurring in distinct paroxysms; the expectoration is copious, frequently from one to two pints in twenty-four hours; the dyspnoea and oppression are almost always more severe than in the previously described species. But when this catarrh is violent it soon threatens suffocation: it commences with the symptoms of a common cold, and in a very few hours the cough becomes excessive and the expectoration enormous; so that as much as three

or four pints have been thrown up in a very short time. The dyspnoea is then extreme, and the patient falls into a state of indescribable anxiety; congestions form, the face becomes livid, the cerebral functions confused, the pulse irregular, and the extremities cold. This affection occasionally attacks infants, and is easily mistaken for croup.

Causes.—The same as those of acute mucous catarrh, but as that species occurs most frequently in bilious temperaments, this happens by far most commonly in those of lymphatic constitutions.

Treatment.—The indications of treatment are the same as in acute mucous catarrh; the same indications and objections to bleeding occur also: emetics are of great use, especially in children, in consequence of the great quantity of viscid filmy secretion which obstructs the bronchial tubes, and which they generally swallow rather than eject by the mouth. Laennec used the tartar emetic in the same manner as I shall describe when we arrive at the treatment of peripneumonia, and with success: he recommends the belladonna and pargories, to diminish the necessity for respiration. Blisters and mustard cataplasms may be used with great advantage.

CHRONIC PITUITOUS CATARRH.

I cannot do better, in speaking of this disease, than follow the admirable description given of it by Laennec.

Chronic pituitous catarrh, like the chronic mucous, is a frequent infirmity of old age, and especially in those of a lymphatic temperament, previously weakened by excesses, or by too sedentary a life: repeated attacks of acute mucous catarrh evidently predispose to this affection. It has been stated, too, that it is not uncommon in old gouty persons, in whom that disease has lost its regular form and some of its intensity.

Chronic pituitous catarrh is rarely a consequence of the acute species—it commonly follows a succession of attacks of the mucous, or dry. When the expectoration is well established, it becomes almost regularly intermittent; there being usually two attacks of cough and expectoration in twenty-four hours—the one on waking in the morning, the other in the evening, and in some immediately after a meal. The quantity is always considerable. Laennec has seen as much as three pints in each access, the duration of which was not above an hour or two, and it is extraordinary how long patients will continue to expectorate so large a quantity: he speaks of an individual, above seventy years of age, who, for ten or twelve years, had brought up every day, in two paroxysms, about four pints of pituitous fluid. I had

a patient at the Lung Infirmary, a young Irishman, who for many months expectorated daily from five to six pints of transparent viscous matter: he ultimately fell a victim to the disease. I suspect that, in these cases, the lungs are always greatly cedematous, for I never meet with them without discovering co-existing crepitation; and in the case I have just mentioned, the whole pulmonary tissue was gorged with colourless serosity.

It is singular that this quantity of expectoration is not incompatible with a certain degree of health, although it continues for years. It is true that after a certain time the patient becomes paler and thinner, but he does not fall into a state of marasmus; he becomes more lymphatic, and the blood, if drawn, shews less consistence; but as old age advances, the accesses of cough are more prolonged and have shorter intervals—the dyspnoea is constant, and he is now called an asthmatic; in fact, it is another form of *humid asthma*: finally cedema of the lungs supervenes, and the catarrh becomes *suffocative*. It occasionally happens that the disease is quicker in its progress, and that the patient falls sooner into a state of great exhaustion and marasmus. It is fortunately uncommon to meet with chronic pituitous catarrh in its exquisite form, although, in a moderate degree, it is by no means infrequent.

Causes.—They are the same as those of chronic mucous catarrh, but, as I have observed before, the disease is most frequent in persons of lymphatic temperaments.

Treatment.—The same mode of treatment should be adopted as we have described for chronic mucous catarrh.

WHOOPING COUGH.

We have now to consider a variety of pituitous catarrh, known under the name of *Pertussis* or *Whooping-cough*. I place it as a variety of this affection, because the secretion is of the same character; although there are essential differences, consisting in the spasmodic nature of the cough, in the spasm of the glottis, in its attacking children more particularly, in its contagious nature, and in its occurring but once during life.

Pertussis, or whooping cough, has received a variety of names: it has been called *tussis convulsiva*, *tussis ferina*, *chincough*, and *kin-cough*.

Morbid anatomy.—The condition of the mucous membrane has not been much observed, but there is no reason to suppose that it differs from its state in ordinary catarrhs; indeed, I have seen it swollen, and reddened in patches, and the bronchial tubes containing a considerable quantity of spumous secretion. When *pertussis*

terminates fatally, it is usually upon the supervention of peripneumonia or œdema pulmonum: in the first case, the lung will be found to contain sanguinolent serum, and here and there a lobule will be found hepatized; in the second, a large quantity of highly spumous and colourless serosity follows the scalpel upon the section of the pulmonary tissue.

Functional signs.—There is a peculiar cough in this disease, which, when once heard, can never be mistaken for any other: it occurs in paroxysms, and consists of a number of saccaded, sonorous, and precipitated expirations, lasting for some minutes, and leaving the patient hardly a moment to inspire; at last a deep inspiratory movement is effected, attended by a prolonged crowing noise, evidently depending upon a spasmodic contraction of the glottis: it is to this noise the term of whooping is applied; and you will observe, gentlemen, that it always occurs during inspiration. After the first whoop, another succession of similar expirations takes place, followed by another whoop; and the paroxysm will continue in this way for a considerable time, until the little sufferer stamps with impatience: his face swells and becomes livid, especially during the whooping; he grasps a chair or any other firm object for support, inclines his body forwards, and at last the fit terminates in a tolerably copious excretion of pituitous fluid, which hangs in films from his mouth: very often the access ends by vomiting. In almost all ordinary cases the patient will return immediately to his amusements, and be as playful and unconcerned as if nothing had troubled him. These paroxysms may occur many times during the day; they are generally observed to be most violent during the evening, and least so at night; and, as the disease proceeds to a favourable termination, the fits of coughing are usually confined to the morning and evening, then to the evening alone, and at last they totally disappear. Pertussis is most uncertain in its duration; for sometimes it runs its course in two or three weeks, sometimes in seven or eight months.

The dyspnœa is always considerable during the paroxysm of cough, and especially towards its termination, even to impending suffocation. In the intervals there is commonly no difficulty of breathing; and when dyspnœa occurs, you may almost be certain of the co-existence of peripneumonia or œdema of the lungs; in either case the danger is much increased. Two or three winters since, pertussis was extremely fatal in the eastern parts of London, and I then invariably found that its fatality arose from the above combinations.

Local signs.—In the intervals of cough-

ing, the ordinary signs of catarrh present themselves; that is to say, the sound on percussion is good, and the respiratory murmur varies on different points of the chest; at one part it is lost; at another, slight; at a third, puerile; and these parts will alternate with each other in the variation; so that, where the sound is at one time inaudible, it will at another be puerile. The various kinds of wheezing are also heard in pertussis; and if peripneumonia, or œdema pulmonum, be superadded, crepitation becomes always distinct at the inferior lobes of the lungs.

During the paroxysm of cough, a singular phenomenon occurs which never could have been discovered positively, except by auscultation. It might be supposed that the lungs would inflate during the strong inspiratory effort of whooping; but not only is the rima glottidis spasmodically contracted, but it would appear that the bronchial tubes are in the same state, for, during the whooping inspiration, and indeed the whole paroxysm, not the slightest respiratory murmur is to be heard; it only appears when the access has totally ceased.

General signs.—Fever rarely occurs, except with peripneumonic combination. If the disease be much prolonged, and the patient be of a weakly constitution, great debility takes place, with hydropic effusions. In many cases the general health is but little affected.

Causes.—Individual.—Pertussis by far most commonly occurs in children; I have, however, seen three or four instances of it in adults: it attacks but once during life.

External.—The common causes of catarrh certainly predispose to whooping-cough, perhaps occasionally produce it; but it most frequently arises from contagion, although Laennec expresses some doubts on that point.

Treatment.—I commence this part of my subject by stating, that there are few diseases more intractable than pertussis. It seems to be an affection that will run a certain course in despite of any means which may be used. Many indications have been pointed out, and many remedies proposed: these remedies, so vaunted, may have been of advantage in some cases, and then it has been inferred they would answer in all; and here let me observe, gentlemen, that we are too much in the habit of generalizing in medicine from isolated facts: the "*Post hoc, ergo propter hoc*" is unfortunately also too common a sophism in medical reasonings. You cannot by possibility be too careful in accumulating a series of facts;—you cannot be too cautious in observing their regularity, and their invariability of succession, so as to determine their relation of cause and effect; and if, by reiterated and scrupulous

examination, you are enabled to form a legitimate induction, so as to establish a general principle or quality pervading a whole class of phenomena, you will indeed have made a great advance in your profession.

So long as there is no dyspnoea or fever, I have but little apprehension of pertussis, but content myself by attending to the general health of the patient, and administering an occasional emetic, by which the viscid phlegm is removed, and perhaps the spasmodic cough somewhat relieved; but I watch closely for dyspnoea, fearing the peripneumonic combination. If that should unfortunately occur, you must be directed by the rules laid down for the treatment of inflammation of the lungs.

When the disease has lasted some weeks, and has become chronic, various means have been proposed—as small doses of opium, or of conium or hyoscyamus, musk, acetate of lead, the recent powder of belladonna, in doses of one eighth to half a grain, or the extract of its root, from the eighth of a grain to a grain: the extract of the narcissus pseudo narcissus has been much extolled, in doses of half a grain to one or two grains every four or six hours: the hydrocyanic acid has been used with varied success; cantharides was formerly a very favourite remedy, particularly when combined with the cinchona: ammonia, ather, and camphor, have all been successively the fashionable remedies.

Various external means have also been employed, as blisters, stimulating embrocations rubbed on the chest and along the spine; but I have so little faith in the use of these, that I shall not fatigue you with their detail, but refer you to the works on medicine for the different formulæ that have been and are still in use.

One of the best remedies is a change of air, although that does not always cure; at least its effects are so slow that it is difficult to attribute the restoration to health to that cause. I had a remarkable proof of this in my own family. Two of my children were seized with pertussis in London; after a fortnight they were removed into Essex, where they remained two months longer with unabated symptoms; I then took them to Paris, and the disease did not finally disappear until they had been there four or five months.

CATARRHUS SICCUS, OR DRY CATARRH.

The generic character of catarrh being an inflammation of the acrian mucous membrane, having for its result a secretion, the expression of catarrhus siccus would seem to imply that it should not be included in that genus; but the term siccus is not to be understood in the positive sense, but in the comparative,

since the disease consists also in an inflammation, having for its consequence a secretion, although infinitely less in quantity than in the preceding species.

Morbid anatomy.—The mucous membrane in this affection is of an obscure red or violet colour; it is swollen, and the swelling more particularly takes place in the smaller bronchial tubes, which are sometimes almost entirely closed by it, although occasionally the membrane lining a larger branch will be thickened to the extent of a few lines, whilst in the continuation of that branch, or in its ramifications, it remains in its natural condition. The extent of the inflammation of the membrane is proportionate to the duration of the disease; yet the whole mucous surface has been thus affected in infancy. When the dry catarrh is universal, or even extensive, it always causes emphysema of the lungs.

The secretion in this disease is very different from that of the other species of catarrh: it consists of an extremely viscid matter, formed into globules, of the size of a pin's head, or larger; they are never mixed with air, are semi-transparent, and of a pearly aspect: this appearance is supposed to depend upon the mixture of a small quantity of the black pulmonary matter; a number of little dark spots are also occasionally seen in the globules. This affection is so common, that many persons, who make no complaint whatever, expectorate a small quantity every morning. These secretions have been named by Fourcroy, *bronchial mucus*; by Laennec, from their similarity to pearls, *pearly sputa*, or *sputa margaritacea*, to distinguish them from the mucous and pituitous fluids.

Local signs.—I shall revert to Laennec's work for the description of the signs of this disease, as it is to him we are indebted for their discovery.

The percussion of the chest affords a perfect sound, but the respiratory murmur is lost, or nearly so, at the points corresponding to the bronchial tubes affected. These points vary when the catarrh is general; for often the parts where, on a first examination, the murmur was inaudible, after a short time present it distinctly. These variations depend upon a greater degree of swelling of the membrane at one time than at another, or upon the varying quantities of pearly sputa obstructing the tubes at different periods.

If the engorgement of the smaller bronchial tubes be not carried to its highest degree, the respiratory murmur may still be heard, although very feebly; and at the same points there will be a slight sibilation or clicking, as if of the opening and

shutting of a small valve; this last sound is least common, and can scarcely be distinguished, except upon deep inspirations or coughing: it depends upon the displacement of a pearly sputum by the air. It is probable that these noises would be louder were it not for the dilatation of the air-cells (emphysema pulmonum), which so frequently accompanies this disease.

Functional and general signs.—A moderate dry catarrh will often remain latent for years. Persons so affected perceive only that their breathing is not so free as that of others when they mount an elevation, or run; but when the tubes become extensively affected, they breathe with difficulty, even in a state of repose, and particularly after a meal: some persons referring the sensation of obstruction to one side of the chest only. At a later period, the accesses of dyspnoea become so severe as to merit the name of asthma; and it is one of the causes of the disease we shall hereafter describe under the name of *dry asthma*. Towards the end of these attacks, cough comes on, and the dyspnoea and oppression diminish; and in a short time a few pearly sputa are expectorated, often floating in a little pituitous fluid, by which the symptoms are still further diminished. In very slight cases, the sputa lose their globular form and density, become more abundant, and are slightly tinged by an intimate admixture of a little yellow or whitish and opaque mucus; at other times they have the consistence and appearance of the vitreous humor of the eye: the *vitreous pitta* of the ancients.

A similar ejection of phlegm occurs habitually in many persons subject to slight degrees of dry catarrh; and if the secretion be not suspended, they are never subject to dyspnoea or asthma. Often the quantity is so small, that they do not observe themselves to expectorate; in others, there is really no cough or expectoration, or the cough is extremely slight and dry, and occurs but once or twice in the twenty-four hours; and then, especially if it has come on slowly, or has not been preceded by acute catarrh, it has been called a *nervous cough*, or it has been supposed to be sympathetic of some other affection, so that it has been denominated *gastric*, *hepatic*, *hysterical*, &c., when, in fact, a local examination of the chest would soon enable us to detect its real cause.

When an acute catarrh is grafted upon the chronic dry form, then the dyspnoea suddenly augments, so as to constitute a fit of asthma; it is relieved by expectoration. Upon a recovery from this state, the habitual dyspnoea is somewhat increased, because the disease has extended further in the course of the bronchial tubes.

It happens occasionally, in nervous persons, particularly in hysterical women, subject to dry catarrh, that a short asthmatic paroxysm will occur upon mental agitation. Thus, I had a patient, who, upon any stranger entering the room, commenced to breathe with great difficulty, and the sibilating wheezing was heard all over the parietes of the chest. After a few minutes, the dyspnoea subsided, and nearly all the sibilation with it.

During sleep, or upon the accidental occurrence of fever, the dyspnoea diminishes, and the instant of waking seems to the patient the only time he breathes freely. Finally, when the disease has lasted a considerable time, emphysema of the lungs and its signs supervene.

Causes.—This is a very frequent disease: persons of all ages and temperaments are subject to it; almost all the inhabitants of maritime and cold countries, or of humid vallies, are constantly attacked by it, although in various degrees; and Laennec asserts that half the inhabitants of the driest parts of France, possessing apparently excellent health, present traces under the stethoscope of some slight bronchial engorgement. From an official situation I hold, I have occasion to examine a number of persons in good health, and there are few indeed who do not present some slight wheezing at one point or other of the chest on a deep inspiration.

Gout, hypochondriasis, certain chronic cutaneous eruptions, are supposed to predispose to this disease.

Dry catarrh is often sympathetic of fever: you generally find the bronchial tubes more or less affected in that class of diseases.

Treatment.—The first indication we should have in view is to diminish the inflammatory action going on in the mucous membrane; but, as in the other forms of catarrh, patients rarely bear general bleeding. If, however, the dyspnoea be great, and the subject plethoric, then bleeding is necessary. I often apply leeches with advantage. Counter-irritants, as blisters, the tartar emetic ointment, Burgundy pitch plaisters, and dry cupping, frequently produce a good effect, although not always a permanent one.

When the cough is violent and distressing, you will find opium produces the most beneficial results, given in doses of a grain, or a grain and a half, at bed-time. Laccine administered it in smaller doses, and repeated them frequently.

Our second indication is to diminish the viscosity of the tenacious phlegm which obstructs the small bronchial tubes. The authors of the humoral pathology imagined that certain medicaments had a solvent effect in these cases. Without repos-

ing any confidence in their hypotheses, I can assert that many of the remedies proposed with that intention do much service. I use frequently the common yellow soap, in doses of from five to ten grains, three times a day. The carbonates of ammonia, soda, and potash, in doses of from ten to thirty-six grains a day, mixed in common drinks, were frequently given by Laennec. The *ippecacuanha* has a very good effect, if long continued. A grain of the powder may be administered three or four times in the twenty-four hours. I have frequently used mercury in severe cases, and am satisfied that, if carefully managed, so as not to excite salivation, it often diminishes the bronchial tumefaction, and occasions a free and diffuent expectoration.

HYSTERICAL COUGH.

Although I have not classed this affection among the catarrhs, still I have placed the description of it here, as it assimilates more to those disorders than any other.

This disease invariably, as far as my experience extends, attacks young hysterical women. I have met with it thirteen or fourteen times, and never in the other sex. It usually occurs before the age of twenty. I have not observed a case beyond the age of twenty-five years. It can hardly be called a cough, it is rather a bark; it is a loud hoarse sound, produced by the act of expiration repeated many times in a minute, for hours, days, weeks; I have seen it continue, with but slight intermissions, for months, the patient having scarcely any relaxation from it but during sleep. The voice is almost always affected; it is generally reduced to a whisper, sometimes to perfect aphonia. A sense of soreness is occasionally complained of about the larynx; the breathing is not always difficult, nor is there always pain or oppression in the chest. The disease is rarely accompanied by expectoration, although in two instances I have seen it combined with pituitous catarrh, and then the quantity of transparent viscous fluid thrown up was considerable; but it was no doubt an accidental coincidence. Sometimes the patients are much distressed and weakened; sometimes they preserve their cheerfulness, appetite, and strength.

I know nothing of the morbid condition of parts in this disease, as I never saw a patient die of it. All I can say is, that there is evidently a spasmodic condition of the respiratory muscles, and of the glottis, depending probably upon some peculiar state of innervation.

Treatment.—This affection seems to be as intractable as pertussis, to which indeed it bears some analogy. I have tried bleeding, blistering, drastic purgatives, iron, and various antispasmodics, and I

cannot say with the slightest beneficial effect. Change of air seems to do more for the patient than any thing else, although you must not consider it as a certain remedy. As the disease is somewhat rare, I will relate the following case.

I was called to a young lady of about 20 years of age, of a sanguine lymphatic temperament, and who had been the subject of hysterical fits. I found she had been coughing unceasingly for five or six weeks, having no remission except during sleep. She had totally lost her voice. She did not appear distressed, but smiled, and looked as if she thought her state rather ridiculous than distressing. A variety of means had been used, but ineffectually. I advised a change of air. She took a coasting voyage, and had hardly got to sea before the barking left her, and her voice returned. She continued this voyage a week, and landing upon some part of the coast, her complaint returned. It diminished, but did not altogether leave her, upon getting to sea again; but on her arrival home she became as bad as ever, and continued so, to the best of my recollection, about two months more, till one morning she suddenly exclaimed, "Mother, I can speak!" From that moment her cough ceased, and her voice returned.

PATHOLOGICAL LECTURES, *

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

V.—On Malignant Tumors of Bone.

IT will not be long before this subject will have received the elucidation which its importance merits. The researches of Mr. Kiernan into the nature of scirrhus, medullary sarcoma, and melanosis, which are likely in a short time to be laid before the Royal Society, will enable pathologists to classify and to describe these diseases on scientific principles, and with scientific precision. And the expected work, by Mr. Stanley, on the diseases of the bones, will enrich this department of surgical literature with the full history of many varieties of disease of which the student can at present glean but scattered and imperfect notices. In the meantime, let me state the comparatively rude but practical views which, in common with others, I entertain upon this subject.

By malignant tumors are meant a class of affections, which consist in the ab-

normal growth of a part through the formation in it of some new element, which has a tendency to indefinite increase,—the increase having no check but in the sloughing or ulceration of the part,—and the disposition to the particular formation being so strong, that it often manifests itself simultaneously in different parts; and often recurs in a part from which the existing disease has once been entirely removed.

Some of the characters, of which the aggregate forms the idea of malignant disease, are separately met with in more than one of the affections, which have been described in my previous lectures.

In persons of the scrofulous diathesis, the tendency to the deposition of tuberculous matter is often manifested at several points of the system at once; and is liable, after the amputation of an affected limb, to develop itself with aggravation in other parts. But in scrofulous disease there is no enlargement of the bone.

In superabundant formation of bone, the tendency to hyperostosis is sometimes, as I have partly exemplified by Mr. Jeff's case, strongly constitutional; the only thing, then, wanted to stamp the complaint as malignant, is the presence of some new substance. No. 533 (dry pathological specimens) in the museum of the College of Surgeons, is a preparation of *ossification of the lungs*, from a person who died through obstructed respiration; the pulmonary symptoms having supervened shortly after the leg had been amputated for a large exostosis of the femur.

Nevertheless, it should be stated *in limine*, as a remarkable point in true malignant diseases in bone, that they have not the malignancy of similar diseases in the soft parts. When a bone attacked with malignant disease is removed, the disease generally does not recur. The same is observed, though less constantly, if in the amputation the section has been made through the sound part of the diseased bone. But, when an amputation is performed for malignant tumor originating in the soft parts, the disease almost certainly reappears.

Malignant tumors of bone are rapid in their growth; the pain which attends them is very variable: it is generally less when the disease originates upon the surface of a bone, than when it commences in the cancelli and has to expand and force open the crust. The countenance in these diseases is commonly pale, and the expression anxious and haggard.

a. *Of Osteo-sarcoma*.—The best way to describe this disease is to call it a cartilaginous exostosis. It consists in a vast growth of substance, nearly resembling cartilage in texture, and originating either

upon the surface or in the cancellous texture of a bone.

A boy broke the first phalanx of one of the lesser toes; a tumor gradually formed on it, which, when it had attained to the size of a sphere, an inch and a half in diameter, gave him considerable pain. He came into the Middlesex Hospital to have the toe amputated. A section of the tumor is in the museum of King's College. It had at first, and preserves, the appearance of a solid sphere of cartilage growing out of the cancelli of the broken bone. There were many small irregular oblong cells in the cartilage, which were filled with a reddish fluid, and at parts the cartilage grated when cut.

A lad, eleven years of age, was a patient in the Middlesex Hospital, under my care. About a twelvemonth before, he had been kicked by another boy upon the shin. The swelling, which immediately supervened, did not subside, but gradually a considerable enlargement formed upon the part of the bone which had been struck. At his admission, the boy was suffering considerable pain, owing to a blister which had been applied over the swollen subcutaneous face of the tibia, and had left the skin red, tense, and raw. The blistered surface was carefully healed, when the pain went away; but the swelling continued to increase, and after some weeks presented the appearance of an extensive conical tumor projecting from the spine and inner and outer aspects of the tibia, the base of which was five inches in length. The rapidity of the growth of the tumor, and the absence of pain, led me to conclude that the disease was superficial osteo-sarcoma, of which I became certain, when, upon puncturing it, I felt the lancet cut through cartilaginous substance. A stream of florid blood flowed briskly from the puncture, but it stopped on pressure, and the small wound readily healed. The boy, understanding that amputation of the limb was now proposed, left the hospital, and returned into the country. The surgeon under whose care he fell performed a different operation: he divided the skin, and exposing the tumor, cut it away from the bone. For a short time every thing went on well; but before the wound was healed the tumor reappeared, and grew with great rapidity, and bled. The surgeon then amputated the limb above the knee; and the patient eventually did well. The amputated tibia, after maceration, was sent to me, with a description of the tumor. From the description, I have no doubt that it was a genuine case of osteo-sarcoma. The appearance of the bone agrees with this supposition: the crust is thin, of a lighter structure than healthy bone,

irregularly excavated upon its surface, and here and there raised into projecting spines and ridges of light bone, which (I conclude in this case, as it is common in others) formed dendritic ossifications stretching into the cartilaginous growth. There was for some time considerable doubt whether the disease was not returning in the extremity of the divided femur. I believe, however, that it did not. Nevertheless, the temporarily suspicious appearance of the stump suggested to me the advantage, in similar cases, of amputating, if possible, at a joint, to avoid the risk of irritating the structure of another bone (as must happen in sawing its shaft), in a constitution liable to malignant osseous disease.

There are two points which are variable in this disease—the quantity of bone in the structure of the tumor, and the number and extent of the cells. In a specimen of osteo-sarcoma in our museum, of which we have a cast of the entire tumor, and the bone after maceration, the upper part of the femur has thrown out a prodigious mass of thin bony plates, which formed a kind of laminated skeleton to the mass of the osteo-sarcoma.

The largest specimen of osteo-sarcoma which I have seen, was in the head of the tibia. The limb was amputated by Mr. Frogley, of Hounslow. The tumor was spherical, and I think nearly a foot in diameter; it contained a large cavity, the crust formed of the osteo sarcoma being from an inch to two inches in thickness.

An osteo-sarcoma grows with great rapidity; its surface is smooth and rounded, and conveys to the touch the idea of its cartilaginous consistence.

There is something in the appearance of osteo-sarcoma, which strongly suggests its affinity to gelatiniform carcinoma.

After the femur and tibia, osteo-sarcoma most frequently attacks the lower or the upper jaw. In either case the disease has been more than once successfully removed by excision either through the sound bone, or at the joint. In the only instance which has fallen under my own care, the disease began in the upper part of the nose, and seemed to be confined to the nasal part of the upper maxillary bone. I removed it; and while the patient continued under my observation, the disease did not recur.

b. Of medullary sarcoma.—It is now about a year since a case of this disease presented itself at the Middlesex Hospital. In the year preceding there were three instances of its occurrence,—two in the head of the tibia, one in the head of the humerus. Amputation was performed in each case, and the patients recovered; and I have not heard that in either a return of the disease has taken place.

One of these cases was under my own

care. In the course of a few months a large swelling of the head of the tibia had formed, attended with considerable pain. A surgeon punctured the swelling, and forced out nearly a pound of yellow doughy substance. Upon this the patient was sent into the hospital, and the limb—the nature of the case being obvious,—was immediately amputated. The head of the tibia was found to be expanded into a thin membranous shell, with very little bony matter in its texture, the cavity filled with a yellowish substance, like the medulla of the brain, and clotted blood. The deposit of medullary substance extended to some distance into the cancelli of the shaft of the bone.

In the other case referred to of medullary disease of the head of the tibia (of which, like the former, the preparation is in our museum), the amputation was performed by Sir Charles Bell. The external appearance of the diseased part was remarkable for its tense brawny hardness. The disease appeared to have begun simultaneously in the cancelli, and upon the surface of the bone. The cancelli contained brainlike substance, or true medullary sarcoma. The crust of the bone was thin, and of a light brittle texture. The muscles of the back of the leg were externally healthy; but near the bone, for their proper texture, there was substituted a firm white substance which came near to the description of Mr. Abernethy's mammary sarcoma; while the hard, brawny, lobulated, subcutaneous tissue on the fore part, might well have been termed pancreatic sarcoma.

It would almost seem that the medullary deposit admits in some instances of absorption; or else there are forms of disease, of which the early history is unknown;—for enlargements of the heads of bones are met with, in which the shell, reduced (as in the preceding instances), to a thin and hardly osseous capsule, contains only gelatinous fluid, intersected with more or fewer membranous septa.

In a remarkable specimen given to us by Mr. Stanley (a section of medullary sarcoma of the femur, amputated by Mr. Earle), there is seen medullary sarcoma that had originated in the cancelli of the bone, and had caused absorption of the crust of the femur, which, when extenuated, had broken. The fracture is surrounded by a large soft tumor; part of this tumor is medullary, part of a firm, white, opaque, fibrous substance, not cartilaginous.

This white, opaque, fibrous substance, may of itself, I believe, constitute a malignant periosteal growth.

In the preceding case it was combined with medullary sarcoma. In another preparation in our museum, for which the leg was amputated by Mr. Green, medul-

lary sarcoma was found in combination with osteo-sarcoma.

The malignant diseases do not attack the round bones. After the large cylindrical bones, especially the tibia, femur, and humerus, the upper and lower jaw-bones seem their most frequent seat.

There is an excellent case related in the 120th number of the Edinburgh Medical and Surgical Journal, illustrating at once the connexion between osteo-sarcoma and medullary sarcoma of bone, and a remarkable feature, which is occasionally developed in the latter disease—a pulsation, namely, as if the tumor were aneurismal. The pulsation is probably communicated from the contiguous arterial trunk.

The patient was a Rosshire farmer, æt. 68. A month after suffering rheumatism of the shoulder, he fell and bruised the part: some swelling ensued, which never disappeared, but in ten months had greatly increased. A pulsation was now first noticed in the tumor; then more rapid growth, and corresponding increase of pain. The skin was not discoloured; the tumor was elastic, but firm; pressure caused little uneasiness, but motion of the arm gave considerable pain. When the tumor was embraced by the hand in all directions, there was a strong pulsation—a distinct feeling of distention—the hand being visibly elevated. This sensation and appearance were much stronger at the more prominent part, over and in the axilla. The humeral artery was distinctly felt high up, but in the axilla the pulsation was suddenly lost, as if in the tumor. To the feel, the pulsation was sawing and peculiar. The operation of tying the subclavian artery was performed on the 17th January; on the 7th February sudden hæmorrhage supervened: death on the 10th.

Upon making a section of the tumor, which consisted of an enlargement of the upper part of the humerus, there was found a conglomerate mass of medullary matter, irregularly intersected with ligamento-cartilaginous bands, and having intermediate cavities throughout, of a dirty-brown colour, which seemed to have been recently emptied of blood. The bone in its whole diameter, for three inches downwards, had entirely disappeared. A very few spicula were felt by the knife on making the section; these, however, were not visible to the eye, and a thin shell of the head, corresponding to the articular surface, only remained. On disarticulation its surface was sound, as was also the scapular cavity, although the ligamentous structures were much thickened.

c.—Melanosis in bone is of rare occurrence. Mr. Kiernan told me he had once met with it, in conjunction with melanotic disease of other organs.

d.—True scirrhus in bone I suppose to be of rare occurrence. I have mentioned that we have a specimen which looks like a scirrhus tumor, in the medullary cavity of the femur of a person labouring under cancer: and there are in London several other preparations of a similar description. But I am not acquainted with an instance of an undoubted scirrhus enlargement of bone.

Mr. Sweatman has a remarkable specimen of scirrhus periosteum. A woman, about seventy years of age, in the cancer ward of the Middlesex Hospital, had carcinoma of the breast. About a month before she died, one eye was observed to protrude, and three days before her death she became suddenly comatose. Upon examining the skull, the dura mater and pericranium, and orbital periosteum, for a considerable extent on the affected side of the head, were found to be thickened and hard: the dura mater was, at one part, a third of an inch in thickness; the arachnoid adhered to it, and partook in the same thickening. The bone is not diseased, but is something more vascular than usual.

In the museum of the College of Surgeons there are several specimens of thickening of the pericranium and dura mater. No. 607 is a section of the right temporal and parietal bones of a young woman, twenty-five years of age. A tumor projects externally, about half an inch above the surface of the parietal bone, and there is a similar tumor situated exactly opposite, on the inside of the skull. These tumors appear, in the preparation in spirits, not unlike that just described, except that the part towards the skull appears opaker than the rest. The opposite section, however, is preserved dried; and the opaker part is thus shewn to consist of short bony threads, in close apposition, which have no continuity with the cranial bones, on which they rest, but must have formed within the tumor. The tumor, I suppose, was malignant. The intervening portion of the cranium is sound, but unusually vascular.

I may add to this lecture, to complete my sketch of the pathology of bone, two points to which I have not yet adverted: one relating to the absorption, the other to the abnormal increase of bone.

1. Bone may be partially absorbed without either atrophy, or inflammation, or caries. Certain kinds of pressure produce this effect. The pulsation of the blood in an aneurism against the ribs, or the sternum, or the vertebrae, causes the gradual removal of the part of the bone on which it tells; but the surface left is not diseased; the aneurismal sac has a kind of adhesion to it.

2. Abnormal growth of a bone may be produced (in addition to the causes before specified) by the formation of hydatids within the cancelli. An interesting case of a bony tumor which contained a considerable number of hydatids, is related by Mr. Keate. The tumor was situated between the two tables of the frontal bone of a female, who was about eighteen years of age. Two operations were performed to remove the tumor, an interval of two years and nine months having taken place between them. During this time, various caustic applications (among which were arsenical preparations and actual cauteries) had been used, but in vain, to destroy the surface from which the hydatids seem to form. On the second operation, in the very hard and compact bony substance which formed the base of the tumor, were found five or six cells, containing hydatid cysts; and these were carefully removed. Sulphate of copper and nitrate of silver were occasionally applied to the whole of the denuded surface, and from time to time produced exfoliations of the bone. In eight months after the second operation the wound healed, and the patient enjoyed perfect health.

PRACTICAL OBSERVATIONS IN MIDWIFERY.

By WM. F. MONTGOMERY, A.M. M.D.

Professor of Midwifery to the King and Queen's
College of Physicians in Ireland, and Accoucheur to Sir P. Dun's Hospital.

On Transverse Malposition of the Head, as a Cause of Difficult Labour.

IN a former communication in the Dublin Journal*, I insisted strongly on the indispensable necessity for a complete and intimate acquaintance, on the part of the accoucheur, with the mechanism of labour, and especially with the exact relations which the different parts of the child's head observe with those of the pelvis, during the progress of a natural labour: by the accuracy of which knowledge alone, and our readiness in applying it in practice, can we hope either to understand the actual condition of any case under our care, or be able to rectify deviations, or remove difficulties, by means at once easy, safe, and effectual, instead of being compelled to resort to the use of instruments, the application of which, however skilfully managed,

must always expose both mother and child to a certain degree of danger, and too frequently gives rise to injuries of a very deplorable kind. If it were necessary by facts to confirm a proposition so undeniable, I could scarcely adduce any which would, in my opinion, more powerfully support its truth, or illustrate the advantages derivable from its adoption, than those on which I now propose to offer a few observations.

I presume I may take for granted, that every one engaged in midwifery practice, has from time to time met with cases in which, while every thing seemed favourably circumstanced, and the labour was apparently proceeding expeditiously to its termination, the head has become suddenly stationary in the cavity of the pelvis, and there remained for many hours, or perhaps until a necessity has arisen for adopting instant means of delivery; and this too when there really existed no deficiency of space to prevent its free passage. The occasional cause of this species of arrest, I believe to be not at all generally understood, which I shall now endeavour to elucidate, by a description of a particular kind of displacement to which I have been in the habit, in my lectures, of applying the name of *transverse malposition*; and by the detail of one or two cases, in which its detection afforded an opportunity of giving instant and complete relief, and happily terminating a severe and protracted state of suffering.

I may just premise, that in the most perfectly natural labour, the head enters the pelvis with its longer axis in coincidence with one of the oblique diameters of that cavity, and with the chin pressed up close upon the chest, until the vertex has descended so low as to press upon the soft parts forming the floor of the pelvis; the occiput then begins to advance towards the arch of the pubis, and the face retreats towards the hollow of the sacrum; next the chin recedes from the chest, and the occiput issuing from under the pubis, the head escapes by revolving, as it were, on a pivot under the anterior wall of the pelvis, so that in this way the head passes through the bony and unyielding chamber of the pelvis, in such a position, that it occupies the least possible dimensions, and the departure of the chin from the chest, which immediately requires greater accommodation, does not take

* Number xiii. p. 52, et seq.

place until the occiput having cleared the confines of the pelvis, has unlimited space to allow of its escape. But occasionally this felicitous arrangement is disturbed, and complete arrest of the head produced by the deviation, which occurs thus: the head having entered the cavity of the pelvis in the position already described, the occiput, instead of moving forwards towards the pubis, recedes towards the spinous process of the ischium, and the face, instead of retreating towards the sacrum, falls into the space between the opposite spinous process of the ischium and its tuberosity; and the chin having receded from the chest, the head is placed, with respect to the outlet, in the most unfavourable manner possible, since it presents to it the greatest possible dimensions which it is capable of assuming, its longest diameter resting its extremities on the opposite tuberosities of the ischia, while at the same time the parietal bone rests on the lower part of the sacrum and coccyx, so that the head is in the condition of a ball supported on three nearly equi-distant, solid, and immoveable points; under which circumstances the action of the uterus, however vigorous, seems totally incapable of either changing the relations thus established, or of effecting the delivery, while they continue as they are. On examining, the finger will pass readily between the head and the pubis, and also posteriorly, except at the point of the sacrum; but there, and opposite the tuberosities of the ischia, the head is felt to be closely locked; the anterior fontanelle is found to be in the centre of the presentation, and the sagittal suture can be traced exactly across the outlet from side to side. How completely and how long this malposition will resist the most powerful action of the uterus, and how easily it may be rectified, will appear sufficiently from the subjoined cases; from which also it will be seen, that this difficulty, (occurring as it does at a time when, from the advanced position of the head, and the state of the perineum and other soft parts, delivery is momentarily expected) is likely to be productive of extreme embarrassment to the attendant, the more especially as the previous birth of full grown children, or even the circumstances of the case, may of themselves afford proof, that there is no natural deficiency of space, since the head may without difficulty be raised from its

situation, to which, however, it immediately returns, and will there remain until the necessary rectification is effected, which should be done in the following manner. Apply two fingers along the junction of the parietal and frontal bones anteriorly; then, in the absence of pain, press up the forehead, and push it backwards towards the sacrum, and there retain it till the access of the next pain, which will in general complete the rectification, and the delivery is speedily accomplished, at least it so happened in the instances which came under my observation. It is scarcely necessary to add, that if, during the descent of the head, a tendency to this malposition be observed, we should at once endeavour to prevent its occurrence, by adopting the means already pointed out as suited for its correction when established; and this I have succeeded in effecting in a few instances.

CASE I.—On Wednesday, July 15, 1829, I was requested to see a patient with the late Mr. Gregory and Dr. Carter; labour had commenced on the previous Monday evening, and proceeded actively on Tuesday; by six o'clock, *p.m.*, the perineum was distended, and the head apparently on the point of being born: in this situation, however, it remained at nine o'clock, *a.m.* of Wednesday, when I saw her; although the uterus had continued to act most energetically the whole of the intervening time, and the soft parts were perfectly relaxed. It was the patient's second labour; she was young, healthy, and well-formed, and had about eighteen months before borne her first child, which was full-sized, after an easy labour of about five or six hours, so that deficiency of space was not probable. On examination I found the head pressing on the perineum; I could pass my finger quite easily between it and the symphysis pubis, but at the sides there was no room at all: the anterior fontanelle was in the centre of the passage, the sagittal suture coinciding with the transverse diameter of the outlet, and the occiput turned to the left ischium: the uterus was acting violently, but produced no other effect upon the head than that of pressing it a little downwards during each pain, on the cessation of which it immediately resumed its original situation. Under these circumstances, I proposed manual rectification of the dis-

placement evidently existing; and having applied my fingers, as already described, along the side of the forehead, I raised and pushed it backwards, towards the right sacro-iliac symphysis, in the interval between two contractions of the uterus; I there retained it, and on the accession of the next pain I repeated the pressure backwards, when the forehead immediately glided to its proper place, at the same time the vertex moved forwards to the arch of the pubis, and *in about two minutes* the delivery was completed by the birth of a fine healthy child.

CASE II.—On the 14th of January, 1834, while lecturing at Sir Patrick Dunn's Hospital, I received an urgent message from Mr. Dunlop, requesting my assistance in a case of obstructed labour, which he had been called to see, and in which, from the extreme violence of the uterine action, he apprehended rupture of the uterus, if the head was not speedily extricated: it was the woman's fifth labour, the four former having been short, and in every respect favourable. In the present instance, symptoms of labour had come on the evening before, the pains had continued gentle through the night, but towards morning they became more active, and at half-past seven o'clock the head was pressing upon the perineum to such a degree that its exit was momentarily expected; but there it remained, without any further advance, when I arrived at half-past eleven, although the uterus had been, during the whole of the intervening four hours, acting incessantly, and so powerfully that its rupture was with great reason apprehended. On examination, I found the perineum and soft parts protruded by the head; they were unusually relaxed and yielding; the head lay across the outlet of the pelvis, with the occiput resting against the tuberosity of the *right* ischium, and the forehead against the left, having probably descended in the second position; there was abundance of space between it and the pubis, *and it could be easily raised into the cavity of the pelvis*, but the next pain instantly forced it back to its resting-place, and when there, the uterine action, although so strong, had no further effect on it whatever. I immediately adopted the same mode of rectification as in the former case, by elevating the forehead

and pushing it round towards the sacrum, when it almost instantly assumed its proper relations under the influence of a pain, *and the very next contraction of the uterus expelled it*; the body immediately followed, and the delivery was completed in *less than two minutes* from the time of effecting the change of position in the head. The child was alive and vigorous. I was fortunate enough in this case to have the valuable assistance of my friend, Dr. Darley, who happened to be with me when I was sent for.

With reference to these cases, it is to be observed, that the subjects of them were women who had already borne children without any difficulty, and that there was evidence at the time, from the circumstances of their cases, that there was abundance of space, as the event fully proved; and yet the obstacle created merely by this kind of malposition of the head was such as to resist, in the one instance for *fifteen hours*, and in the other for *four*, action of the uterus, so powerful that it effected the delivery almost the very instant that the displacement was corrected.

As to the cause of this malposition, I am not prepared to offer any satisfactory explanation, nor is it, as far as I can see, a matter of the least consequence. The idea of Levret, that such misplacements of the head were caused by the situation of the placenta, is so unsupported by either facts or reasoning, and is indeed so fantastic, that I think we may dismiss it at once without further consideration. Neither is the hypothesis, which would explain them by obliquity either of situation or action of the uterus, in any degree more satisfactory. Rœderer ascribes some such deviations to misdirection of the shoulders, which he supposes in such cases to be placed across the smaller diameter of the brim; that this may be so occasionally is not improbable, but in the particular species under consideration, I think it certainly is not the case, because we can so completely correct it, merely by changing, and slightly too, the position of the head without moving the child's body at all. One thing, however, is certain—that when the malposition has taken place, the chin of the child has receded from the chest, and the forehead has sunk as low as the occiput, and that its re-elevation is essential to the rectification, and must be accomplished before

delivery will take place; for while the transverse position continues, the natural efforts will not be sufficient, the forceps will not answer our purpose, and turning is out of the question; so that if the real nature of the case be not recognized, recourse will be almost certainly had to the appalling operation of cephalotomy, and a human life unnecessarily sacrificed. It seems very reasonable to suppose that an unusual projection or curvature of the spinous process of the ischium might have the effect of producing this accident, because, under such circumstances, the forehead being prevented from gliding backwards, and being still acted on by the uterine contractions, would almost of necessity be forced downwards into the situation where we find it in such cases, and the occiput would, of course, assume the corresponding situation at the opposite side of the outlet.*.

OBSERVATIONS ON INTERMITTENT FEVER.

To the Editor of the Medical Gazette.

SIR,

THE following observations would have reached you long ere now, had not an unexpected call withdrawn me from home. Should you now deem them worthy of a place in your Gazette, their insertion will oblige

Your obedient servant,
AL. PATERSON.

Maçero, Brazil, Oct. 1, 1834.

Of forty-one cases of intermittent fever which occurred on board the H. C. ship Barrosa, in the years 1832-33, three took place from seventy to eighty-three days after leaving England; thirty-one while lying at Whampoa; and seven from two to three months after our departure from Canton, and ninety-three days after ague had ceased to manifest itself in the ship.

Whampoa being a situation peculiarly adapted for the production of marsh miasms, we may reasonably infer that it was the principal cause of the agues which there prevailed, but it con-

tributed nothing to the production of those which occurred at sea, since these did not show themselves until the vessel was widely distant from all miasmatic influence. I stop not, at present, to inquire into the probable origin of these latter cases, but hasten to remark, that they were in no way connected with organic affections, and that they demonstrate the truth of the generally received doctrine, that "febrile miasm arising from marsh lands is the most common cause of intermittents, but by no means the only external agency capable of producing them."

It has been the practice of many to prescribe a great number of medicines in the paroxysm of intermittents, more with a view to alleviate the febrile attack than to prevent its recurrence. But since a return of the fit may, in most cases, be prevented by proper treatment during the intermission, and since the medicines serviceable in one stage of the paroxysm are generally injurious in the others, often exerting a noxious influence on the whole course of the disease, medical operations ought to be confined to the season of intermission, except where the unusual severity of any particular symptom demands immediate interference. The high authority under which "bleeding in the cold stage" has been introduced to the notice of the profession, may appear to exempt it from this remark. As far as my own experience enables me to judge, I must say, that it has always appeared to lengthen the convalescence, without producing any decided benefit, except where the disease was accompanied by organic affections, when bleeding will be equally efficacious, and more conveniently performed, at another period.

The intermission being, then, the most important season for medical interference, I pass on to detail the comparative advantages of a few of the remedies then generally used. The most valuable of these is the sulphate of quinine, ten grains of which are to be taken every three hours during the intermission of a quotidian. In tertians the dose should be diminished, and the interval increased, to five grains every six hours. In quartans the interval may be still longer. When a recurrence of the fit has been prevented, it will be sufficient to take five grains twice a day during the first week, and once a day

during the second, in order to guard against a relapse.

The remedial power of quinine is much greater when administered in this manner, than when one or two large doses are taken a little before the expected paroxysm; for although these subdue the disease, the convalescence is commonly protracted by vertigo, disorder of the digestive organs, and irregular action of the sanguiferous system—effects often produced by dietetic irregularities, and more frequently by the common practice of administering this remedy in conjunction with wine or spirits—a practice founded upon an erroneous pathology, and deserving of the severest reprobation. It is also not unimportant to remark, that when quinine has been properly administered, and attention given to regimen, cathartics are rarely proper, as they tend to interfere with its action, and to debilitate the patient. The white and furred tongue so common in this class of diseases, being indicative of nervous irritation, does by no means authorise the use of purgatives.

In thirty-two cases in which I prescribed the quinine as above, a second febrile attack was prevented, except in two, and these were complicated with disease of the liver and enlargement of the spleen. In three cases, mxx of the liquor arsenicalis, and in two, mxx , were administered at the same periods as the quinine. In three of these the paroxysm recurred thrice; in one, four times; in the fifth, irritability of the stomach and bowels forbade a continuance of the remedy. Two drachms of bark were, after a like manner, given to four patients, of whom two had a second, and two a third febrile attack. In all these cases the debility was greater, and the convalescence much more protracted, than when quinine was used; and it did not appear that any one of the remedies exerted a greater power than the others in fortifying the constitution against a relapse.

I may add, as I close this short paper, —the practical inferences from which are sufficiently obvious,—that since my arrival in Brazil, daily experience convinces me that the above cases exhibit a result which may ordinarily be expected.

CASE OF CONGENITAL MALFORMATION.

To the Editor of the Medical Gazette.

SIR,

AN unusual example of congenital malformation having lately come within my observation, I beg leave to forward a brief account of it for the columns of your journal.

Mrs. R. æt. 25, the mother of three children, was taken with her fourth labour, after a gestation (according to her own account) of forty-three weeks. Mr. Holroyde, of this town, was summoned to her aid, and in the course of a couple of hours she was delivered of a small but well-formed female child, to whom attention was soon particularly drawn, from the continued gasping character of its respiration, and the circumstance of the heart's pulsation, instead of being felt at the usual site, being observable at the right side of the chest.

After living upwards of an hour, although every appropriate means were used, the child ceased to breathe. On the following day an inspection was made by Mr. Holroyde, in the presence of Mr. W. B. Stott, two medical pupils, and the present writer, when the following appearances presented themselves.

The heart (the pericardial envelope of which was more vascular than usual) was observed lying on the right side, between the fifth and sixth ribs, and compressing the three pulmonary lobes, which, upon examination, were found to be extremely small, and partially inflated, but apparently quite healthy. The same side of the chest contained about two ounces of serous fluid. The left cavity of the thorax was occupied by its two pulmonary lobes (small and dark coloured), the smaller lobe of the liver, the stomach, the spleen, the whole of the small intestines, and a great part of the larger ones.

In the abdomen, the right lobe of the liver (somewhat darker than I have generally seen it in new-born children) and the descending portion of the colon, apparently enlarged, presented themselves.

Upon proceeding to more minute examination, we found the *left wall of the diaphragm, posteriorly, entirely wanting*: not that the muscle presented an aperture admitting hernial protrusion,

but was (that portion of it) congenitally absent. Hence the position of parts; hence the mechanical obstruction to respiration; and hence the subsequent death of the child.

The kidneys, bladder, uterus, &c. it is scarcely necessary to add, were healthy, and *in situ*.—I am, sir,

Your obedient servant,

JOHN ALEXANDER, M.D.

One of the Medical Officers to the General Dispensary for Children, Manchester.

November 16, 1834.

ON

BELLINGERI'S CLAIMS AS A PHYSIOLOGIST.

To the Editor of the Medical Gazette.

SIR,

THE musical world expressed great delight at Paganini's reiterated performance upon one string. The physiological world has been now for a long period amused,—to tiring, I am afraid,—with a parallel display. What the fourth chord of the fiddle was to Paganini, the “uses of the nerves” have been to more than one physiological performer.

Of those who have harped upon this string, Sir Charles Bell has produced the grandest composition: he has sounded every note, from the octave of the cerebral nerves to the cauda equina. Unfortunately, however, for his permanent fame, his best parts are the appropriated thoughts of others, which gives a sort of falsetto quality to his performance, that captivates the vulgar, but displeases a correct ear.

My own composition upon this string is in three parts. The first is the restoration of the true and original movement of Sir Charles Bell, beginning with the murmurs of the respiratory system, throwing instinctive expression upon the seventh, and playing a voluntary with feeling upon the fifth—the voluntary and the feeling being repeated on the anterior roots of the spinal nerves, and sympathy and the modulation of vegetable life (or the organ stop) being exemplified in the posterior roots. The second (to leave jesting), is the vindication of my own discovery—that the facial branches of the fifth minister exclusively to sensation, and that the portio dura is the source of every mode

of muscular action observed in the face, whether instinctive or deliberate*. The third is the rendering to Magendie the credit, to which he is entitled, for having first experimentally proved that the anterior roots of the spinal nerves are for motion, the posterior for sensation.

The Edinburgh Medical Review has recently advocated the claims of another. A very able writer in that excellent journal, after giving deserved praise to Bellingeri's anatomical inquiries respecting the nerves, has asserted that *he* was likewise the first to make out their physiology. I find, however, upon a careful examination of Bellingeri's thesis, that this opinion is incorrect. Bellingeri's views of the functions of the nervous system were ingenious, but, like Sir Charles Bell's, erroneous. Bellingeri attributed to the facial branches of the fifth both sense and motion, like Sir Charles Bell; but, in addition, he attributed *both the same endowments* to the seventh; drawing very curious but false distinctions between the supposed endowments of the two. Of the spinal nerves, Bellingeri considered the anterior roots to be the source of *flexion*, the posterior roots, of *sensation* and *extension* jointly. I have subjoined, in reference to the cerebral nerves, the extracts from Bellingeri necessary to prove the correctness of my statement.—I remain, sir,

Your obedient servant,

HERBERT MAYO.

CHARTER

OF THE

ROYAL MEDICAL & CHIRURGICAL SOCIETY OF LONDON.

[SEVERAL correspondents having begged for further information regarding the incorporation of the Medico-Chirurgical Society, we have thought the best plan would be to insert a copy of the Charter.]

WILLIAM THE FOURTH, by the Grace of God of the United Kingdom of Great Britain and Ireland King, Defender of the Faith—To all to whom these presents shall come, Greeting:

WHEREAS John Elliotson, Doctor of Physic, Sir Astley Paston Cooper, Baronet, and John Yelloly, Doctor of Physic, have, by their petition, humbly represented unto us that a Society was formed in the year one thousand eight hundred and five by a considerable number of physicians and surgeons of eminence in London, for the cultivation and promotion of physic and surgery, and of the branches of science connected with them, of which the last two named

of the petitioners were original members; and that the said Society has expended considerable sums of money in the purchase and collection of a large and valuable Library, and has published eighteen volumes of Transactions which have had a very extensive circulation. And whereas they the said petitioners have humbly besought us that we should give to them and to the other persons who have already become members of the said Society, or who may at any time hereafter become members thereof, our royal charter of incorporation for imparting greater stability and effect to the designs of the said Society. Now know ye, that we, being desirous of encouraging a design so laudable, have of our special grace, certain knowledge and mere motion, willed, granted and ordained, and do by these presents for us, our heirs and successors, will, grant and ordain that the said John Elliotson, Sir Astley Paston Cooper, and John Yelloly, and such others of our loving subjects as are now members of the said Society, or who shall at any time hereafter become members thereof, according to such bye-laws as shall hereafter be framed or enacted, shall by virtue of these presents be called Fellows of the said Society, and shall be one body politic and corporate, by the name of *The Royal Medical and Chirurgical Society of London*; of which Society we do hereby declare ourselves and successors if they shall think fit, the Patron, by which name they shall have perpetual succession, and a common seal with full power to alter, vary, break and renew the same at their discretion, and by the same name to sue and be sued, to implead and be impleaded, to answer and be answered unto, in every court of us, our heirs and successors, and be for ever able and capable in the law to purchase, receive, hold, possess and enjoy to them and their successors any goods and chattels whatsoever, and also be able and capable in the law (notwithstanding the statutes of mortmain) to take, purchase, hold and enjoy to them and their successors any lands, tenements or hereditaments whatsoever, the yearly value of which shall not exceed in the whole the sum of two thousand pounds, computing the same respectively at the rack rent which might have been had or gotten for the same respectively at the time of the purchase or acquisition thereof; and shall have full power

and authority to sell, alien, charge or otherwise dispose of any real or personal property so to be by them acquired as aforesaid, and to act and do in all things relating to the said corporation in as ample manner and form as any other our liege subjects, being persons able and capable in the law, or any other body politic and corporate in our said United Kingdom of Great Britain, may or can act or do.

And we do further declare and grant that for the better government of the said Society and for the better management of the concerns thereof, there shall be, from the date of these presents thenceforth and for ever, a President of the said Society, who with twenty Fellows to be elected in manner hereinafter mentioned shall form the Council. And we do hereby appoint the said John Elliotson the first President of the said Society, and the said Sir Astley Paston Cooper and John Yelloly the first members of the Council, to continue in office till the first day of March next. And we further direct that within four months from the date of these letters patent, a general meeting of the Fellows of the said Society shall be held, who shall be authorized by method of ballot to elect eighteen fit and proper persons as officers and other members of the Council, to complete the number of twenty-one, of whom including the President we have willed that the Council shall be composed, and that such additional persons shall likewise continue in office till the first day of March next, and till other fit and proper persons be chosen in their room.

And our further will and pleasure is, that the Fellows of the said Society shall and may on the first day of March one thousand eight hundred and thirty-five, and also shall and may on the first day of March in every succeeding year, or as near the same as conveniently may be, assemble together at the then last or other usual place of meeting of the said Society, and proceed by method of ballot to nominate and appoint a President of the said Society, and such officers and other members of the Council as may with the President form the number of twenty-one, of whom we have willed that the Council shall consist; and also may in case of the death, resignation or removal of the President or any officer or other member of the Coun-

cil within the space of three months next after such death, resignation or removal, elect some other person being a Fellow of the said Society to supply the place of such President or officer or other member of the Council. And our further will and pleasure is, that no Fellow who has filled the office of President for two successive years shall be again eligible to the same situation until the expiration of one year from the termination of his office, and that not more than two-thirds of the Fellows who have formed the Council of the preceding year shall be re-elected members of the Council at such annual meeting. And we do further grant and declare that the Fellows of the said Society or any ten or more of them shall and may have power from time to time at the meetings of the said Society to be held at the usual place of meeting of the said Society, or at such place as shall have in that behalf been appointed, by and with the consent of not less than four-fifths of the Fellows present, to elect such persons to be Fellows of the said Society, and all Fellows to remove from the said Society, as they shall think fit; and that the Council hereby directed to be appointed and the Council of the said Society for the time being or any three or more of them, all the members thereof having been first duly summoned to attend the meetings thereof, shall and may have power according to the best of their judgment and discretion to make and establish such bye laws as they shall deem proper and necessary for regulating the affairs of the said Society, and also the number and description of its officers, and also the times, place and manner of electing and removing the Fellows of the said Society, and all such subordinate servants, officers and attendants as shall be deemed necessary or useful for the said Society, and also for filling up from time to time any vacancies which may happen by death, resignation, removal or otherwise in any of the officers or appointments constituted or established for the execution of the business and concerns of the said Society, and for regulating and ascertaining the qualifications of persons to become Fellows of the said Society respectively, and also the sum and sums of money to be paid by them respectively or any of them, whether upon admission or otherwise, towards

carrying on the purposes of the said Society, and also the number, qualifications and privileges of such persons as they may from time to time deem it proper to admit as honorary Fellows; and such bye laws from time to time to vary, alter or revoke, and make such new and other bye laws, as they shall think most useful and expedient, so that the same be not repugnant to those presents or to the laws of this our realm: provided, that no bye law hereafter to be made, or alteration or repeal of any bye law which shall hereafter have been established by the same council hereby directed to be appointed, shall be considered to have passed and be binding on the said Society, until such bye laws or such alteration or repeal of any bye laws shall, after such notice to the Fellows as from time to time may be deemed expedient by the said Society, have been confirmed by ballot by the members at large of the said Society, ten at least of the Fellows of the said Society being present: and provided that no such bye law or alteration or repeal of any bye law shall be deemed or taken to pass in the affirmative, unless it shall appear upon such ballot that not less than two-thirds of the Fellows present at such meeting shall have voted for the same. And our further will and pleasure is, that it shall be lawful for any three Fellows, by writing under their hands transmitted to the President or such other officer or officers as may by the bye laws hereafter to be made be designated for the purpose, to recommend to the council any new bye laws or alteration or repeal of any existing bye laws; and in case the council shall not agree to such new bye laws or alteration or repeal of any existing bye laws, then our will and pleasure is that such propositions shall, if required by the said three Fellows, be submitted to the consideration of the Society at large, and determined on by them in the same way as has been directed with regard to new bye laws or alterations or repeals of existing bye laws which have been approved by the council. In witness whereof we have caused these our letters to be made patent. Witness ourself, at our palace at Westminster, this thirtieth day of September, in the fifth year of our reign.

By Writ of Privy Seal
EDMUNDS.

publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL ORGANIZATION IN AUSTRIA.

In a subsequent page will be found a document which we read with much interest; and it strikes us that many of our readers will be obliged to us for laying it before them. On various occasions we have noticed the arrangements of the profession in other European states, and particularly, in the course of the present year, we gave an ample detail of the reformed system in Prussia. Relative to the medical affairs of Austria, a nation occupying so distinguished a position among the more enlightened countries of Europe, we were anxious for a trustworthy, and, as much as possible, an official account; this we are glad to have obtained at last, through the praiseworthy diligence of our Belgian contemporary. It will be duly appreciated, we doubt not, by all who peruse it—more especially the first part, respecting medical education, and the modes by which a supply of well-qualified practitioners for the Austrian States is secured. The other portion, concerning the arrangement of the profession throughout the different parts of the empire, will perhaps be considered more as matter of curiosity than of utility. It is so unlike anything ever even contemplated in this country, as desirable in the adoption, that most readers cannot fail to be at least struck with the novelty, as well as contrast to our system, which it affords.

The educational machinery of Austria is simple and well arranged. Making all due allowance for the difference between it and the mode which has so

successfully prevailed among us for so many years, we can sincerely admire the sort of discipline laid down for the Austrian student. We think it superior to that of either France or Prussia, as affording a suitable curriculum for the general practitioner. In Prussia, it is true, the preliminary education in arts required of medical aspirants to the Doctorate, renders that class perhaps higher in intellectual attainments of a general nature than any similar body to be found on the continent; but for the ordinary, and most generally useful, class of practitioners, the education appointed in Prussia is certainly inferior to that in Austria. In the latter country there are not those various and distinct courses which are prescribed in the former, for each class of practitioners, according to the object which he may choose to have in view—whether he will graduate as a practising physician, or seek a diploma as a surgeon of the first class, or as a surgeon of the second class—whether he will practise in town, or be content with the provinces—for in all these circumstances the requisite education is respectively modified. But in Austria there is one common course of professional discipline, at least up to the period of selecting which branch the candidate will adopt for practice; and that common course is of a most ample and comprehensive kind. With a preliminary education equal to that required on entering the medical schools of Paris, the Austrian has a decided advantage over the French arrangement for professional education, if it were only in the additional year devoted to it in the former country; the curriculum in Austria occupying a period of five years, while that in France requires but four.

If certain of our reformers in this country were really desirous of “leveling upwards,” we could not propose to

them a better standard, or model of imitation, than the Austrian system. It seems not unsuited, too, to become their *beau ideal* in another particular, inasmuch as it approaches their grand desideratum of a single faculty; and they find in it, moreover, a metropolitan body conferring degrees in the two great branches of the healing art. We could ourselves, indeed, be even content with the adoption of some such system among us; for it exhibits in actual practice that sort of projected alteration of which we have all along been the advocates. All the requisite studies are pursued in the metropolis—all the necessary qualifications, literary and professional, are there attained—and there, too, is (as we would have it) the final verdict of competency pronounced by a competent tribunal.

There are, however, one or two points in the Austrian arrangements which we should be glad to see modified. Among the examiners, for example, at the final ordeals (the *Great-goes* we suppose we may call them), we would not have any of the actual professors appointed. The arbiters of the student's competency should not be those who are in daily habits of intercourse with him as his teachers: though the system which prevails on the continent, of paying the pupils' fees into the government purse, and remunerating the professors by salaries, takes off much of the objectionableness of the proceeding to which we allude. Here, in this country, most undoubtedly, under any new arrangement that may be adopted, the possibility of one and the same set of men being both examiners and teachers were perfectly inadmissible. In point of qualification for so important an office—abstractedly from the partial influences which might come into play—few, we are aware, ought to be considered as

better adapted for the task of gauging the candidates' acquirements; but the very suspicion attaching to the circumstances, would, in the end, place in a stronger light the necessity of placing none in the chair of judge who had not previously resigned that of the professor.

The repeated examinations—weekly, semestral, and annual—to which the students are obliged to submit, in order to give proof of their progress, or otherwise be thrown back as incompetent, are all excellent in their way, and worthy of imitation wherever there are schools of medicine established.

With respect to that part of the paper which relates to the organization of the profession, we have but few remarks to make. It is, as we have said, curious, and perhaps, for a country governed as Austria is, the best suited to the circumstances. There are not those numerous grades and orders of practitioners recognized there which we find in Prussia; but the appointments of provincial and district state medical officers are on fully as adequate a scale as in the latter country, and commissioned as if the whole population of the land constituted but *one great army*. The care bestowed on the public health by the Austrian government is truly admirable, and many of the measures ordained for the purpose cannot but be ultimately productive of much benefit to medical science. We allude more particularly to the annual reports required of the *Proto-Medici*; containing minute particulars of every thing relating to the salubrity of their respective provinces, and including the hospital returns, remarkable cases, observations, &c. Such a mass of information, well drawn up, must prove of the highest value at some future day, when scrutinized and digested by a Van Swieten, a Hildebrand, or a De Haen.

There is one remarkable duty connected with the office of the Austrian *Proto-Medicus*, which the reader will not omit to notice; and that is, the exercise of a *censorship* over the medical press. By the terms of his commission, this officer must look to the purity of the medical journals from all matter of political import or tendency: he must inspect the manuscripts of professional authors, who in their turn are obliged to submit their papers for his approval previous to publication. This is, it must be confessed, rather an odd precaution against treason—it certainly passes all our experience; for who ever heard of a political squib shot off in the shape of an hospital report, or even of disaffection to the body politic being couched in an account of the affections of the body corporate? It may be that the Austrian legislator thought it rather suspicious that there should be so much said in medical books about the *constitution*, the necessity of altering the *regimen*, and of *letting blood* freely at certain times. But however it be accounted for, it is well we have not the felicity of being supervised by an Austrian censor: for we, as well as most of our brethren, have the name of being political—though how the fact could be proved against us we have not an idea. Were we at this moment to write an article founded on the *dismissal of ministers*, and to draw our inferences, or hazard our predictions, relative to the chances of a certain stock-jobbing establishment obtaining a charter from the new administration—supposing for a moment that it ever had a chance of one from the old, we should fairly lay ourselves open to the charge of being political partizans. But as we never indulge in these speculations, we shall not permit ourselves to say more on the subject at present.

PRESENT SYSTEM
OF
MEDICAL EDUCATION,
AND
THE ARRANGEMENT OF THE MEDICAL
PROFESSION,
IN THE
AUSTRIAN STATES.

THE laws by which the profession in Austria is governed, were enacted in the reigns of Maria Theresa, of Joseph II., and of the Emperor Francis I. The object is the improvement of medical education in the schools, the supplying of suitable practitioners for the people, and the regulation of the *pharmaciens*, who alone are permitted to deal in drugs and medicines. They further contain clauses of great severity for the checking of charlatanism; and in order that the magistrates may be fully acquainted with every thing relating to hygiene and medical police, appointments are provided in the several districts

for a body of well-instructed and experienced medical persons, specially entrusted with this duty.

I. SYSTEM OF EDUCATION.

There is no distinction made, in the Austrian universities, between the education of physicians and that of surgeons. The students destined for either pursuit must attend the courses of both branches of the healing art, and not until they have completed their curriculum are they allowed to choose which they shall practise: but they may practise both if they choose, and be found properly qualified.

The qualification for a doctor of medicine or surgery, consists in a five years' attendance of lectures in some national university; the three first years being devoted to the study of the collateral sciences and the theoretical parts of medicine, and the last two being employed in special therapeutics and practice, at the bed side of the patient. The following is the order in which the several branches are studied:—

First Year...	1st Semestre.	{ A general introductory course of medicine and surgery. A course of anatomy. A course of special natural history.
	2d Semestre.	{ The courses of anatomy and natural history repeated. A course of botany.
Second Year.	1st Semestre.	{ Anatomy and physiology of a more advanced character. General chemistry.
	2d Semestre.	{ Anatomy and physiology continued. Pharmacy and animal chemistry.
Third Year.	1st Semestre.	{ 1. General pathology (etiology, semeiology, and general therapeutics). 2. Materia medica and chirurgica, dietetics, and art of prescribing. 3. Theoretical surgery (general and special pathology of surgical disorders). Midwifery.
	2d Semestre.	{ Courses 1, 2, 3, preceding, continued. Bandages and surgical instruments, from June till the end of the medical year.
Fourth Year.	1st Semestre.	{ 1. Special therapeutics of internal maladies. 2. Internal clinique.
	2d Semestre.	{ 1 and 2 preceding continued. Veterinary medicine.
Fifth Year.	1st Semestre.	{ 1 and 2 of preceding year continued. Forensic medicine
	2d Semestre.	{ 1 and 2 continued. Medical police.

It is to be observed, with reference to clinical instruction, that, both in Austria and Prussia, students who have completed

their theoretical courses are divided into practising pupils and assistants; the former being entrusted with the treatment of a

certain number of patients, whom they visit under the inspection of the clinical professor. If they acquit themselves well, he does not interfere; if not, he instructs them in the questions which they ought to put. After each visit, the professor interrogates the pupil as to the class, order, and species of the malady, the prognosis, and the indications. If the pupil be right, he is requested to prescribe aloud. An assistant is attached to each practising pupil, who goes round with him, and in the course of six months becomes a practitioner himself.

The lectures on physiology, pathology, *materia medica*, and special therapeutics, as well as the clinical remarks at the patient's bed-side, are delivered in Latin: in all the other courses the German is the language employed. In Hungary, Poland, and Italy, the language of each country respectively is used.

Previous to admission to the medical schools, the pupil must produce a certificate of having attended a three years' course of humanity in some national school; and pupils are arranged, in general, in three classes; the first consisting of those who have answered best, and obtained the title of *eminent*, the others according to their respective merits. Diligence and moral conduct are high recommendations in the certificate for admission: in fact, the law expressly declares that this must be seriously attended to, in order to exclude, as much as possible, from the study of an art so important and difficult as that of medicine, all those who are not more or less distinguished by their attainments and good conduct.

Matriculation is not attended with any expense.

Students are forbidden to smoke cigars, or to frequent drinking-houses.

No student can advance to a higher class without having attended that immediately preceeding it; and he must pass an examination. If his answering be but second-rate, he must go through his last courses again; and if upon another trial he be found deficient, his name is erased from the list of medical students, and he is precluded from entering any other national university.

Every professor is bound to examine his class once a week publicly, for at least half an hour. The results he must note down, for the better arrangement of the classes. At the end of every semestre, the pupils are examined in their previous courses: the first examination takes place in the latter part of March, the second towards the end of August; the particular day and hour being announced a month previously. The director and a commissioner of instruction are obliged to attend at these trials; and

the professors are enjoined by the law to be as strict as possible, and not to allow themselves to be carried away by an ill-judged indulgence. It is during the first year they are expected to be most severe, in order to get a timely riddance of those students who are dull or negligent, and to secure the state against the danger of having ignorant physicians or surgeons admitted to practice. In the certificates given on these occasions, not only the abilities of the pupil are set forth, but his moral conduct is noted.

The fees paid by each student amount to 30 florins (about 3*l.*) a year—3 florins a month. These charges go chiefly to the support of a certain number of poor but respectable students, who belong to large families of straightened means, and are distinguished for their diligence and good behaviour.

In order to be admitted to the final examinations, the pupil must shew that he has acquitted himself well at the weekly ones, as well as at those at the end of each semestre. The Dean of the Faculty is obliged to pay special attention to this rule, or otherwise forfeit 20 florins to the general fund. Two students cannot be examined at the same time. The judgments of reception are *Satis Bene*, or *Valde bene*. If two professors vote for the candidate's rejection, he must be examined over again at some future time, going through certain courses prescribed to him in the interval. If he decline this, he is not entitled to have his examination fees refunded to him; but if he submit to a second trial, he has nothing additional to pay. Not so, however, if he be rejected a second time: he must pay his fees afresh for a third examination. Nobody can be examined more than three times: a third rejection disqualifies the candidate from ever practising in Austria.

Previous to the admission of the candidate to examination, he must produce an account of two medical cases treated by himself, and also a report in legal medicine. These papers must be forwarded to the Dean, who communicates them to the examiners, and upon their approval the candidate is admitted to the final rigorous examinations.

The rigorous ordeals for the diploma are two in number. The first is an examination in anatomy, botany, natural history, physiology, general and special pathology of external and internal diseases, semiology, and general therapeutics. The examiners are the Dean, the President of the Faculty, and the professors of anatomy, botany, natural history, physiology, and pathology.

For the second, the subjects are, chemistry, forensic medicine, ophthalmology,

materia medica, art of prescribing, and clinical practice; and the examiners are the professors of chemistry, forensic medicine, ophthalmology, and materia medica, together with a physician unattached to the faculty. In Vienna, the latter person is the vice-director; and in the provinces, some practising physician, not a professor.

The candidate may answer, as he pleases, either in Latin or in the vernacular.

Having passed these examinations, he is obliged to write a dissertation on a medical subject. He must also add some theses, which he has to defend publicly against three disputants—doctors of medicine or surgery. The Dean, and the President of the Faculty, as well as four professors, must attend the reading of the dissertation, and copies of it are to be distributed to all who may be present: the said dissertation and theses being written and defended in German, if the Dean grant leave; but this is not very usual, nor without some reasonable pretext.

The expenses of these final *rigorous* examinations are—for the first, thirty-five florins, five florins being paid to each examiner; for the second, sixty-three florins, nine florins to each examiner. The fee to the censorship, exercised by each of the professors in turn, is four florins fifty kreutzers; for the admission, &c. sixty-nine florins; to the president of the dissertation, twenty-seven florins: in all, 199 florins (nearly 20*l.*)

If the candidate seek the diploma of doctor of surgery—1, He must be examined in anatomy, chemistry, materia medica, the art of prescribing, forensic medicine, ophthalmology, and the theory and practice of surgery; 2, He must perform two operations on the dead body publicly, and in presence of all the professional men and pupils who choose to be present. Previously to operating, he must give a history of the process which he is about to adopt, describe it, point out the different modes in which it may be performed, distinguish the several advantages and disadvantages of each mode, note the indication and contra-indication, shew how the instruments and bandages are to be employed, &c.: in short, he must act with all the care and attention he would use with the living.

The expenses of these examinations for the surgical diploma are—for the first, seventy-two florins—of which the seven senior examiners receive nine florins each, the junior half that sum; for the second examination, the candidate pays fifty-four florins, nine florins to each examiner. The admission is sixty-nine florins thirty kr.; and the sum total, 195 florins 30 kr. (about 19*l.* 10*s.*)

If a doctor of surgery wish to obtain the degree of doctor of medicine, he must be examined—1, in botany, physiology, natural history, general and special pathology, therapeutics, and semeiology of internal diseases; 2, in practical matters relating to internal medicine. For both these examinations, the dissertation, and the admission fees, &c., the expenses are 111 florins 30 kr. (about 11*l.* 10*s.*)

If a doctor of medicine wish to be admitted to surgery, he must be examined—1, in the theory and practice of surgery; 2, in the public test required of every candidate for the surgical diploma. The expenses are 110 florins (about 11*l.*)

Non catholic candidates are admitted to degrees by dispensation only; but then there is no oath administered at variance with the religious tenets or observances of the parties.

2. ORGANIZATION OF THE PROFESSION.

We have now to give an account of the arrangements of the medical profession throughout the States. The supreme direction of every thing that relates to the general organization of medical affairs, is committed to the Chancery of the court of Austria. In the provinces, it is entrusted to the provincial officers (*Landesstellen*), who, however, are obliged to have recourse to the Chancery in all matters of importance. As all kinds of quarantine regulations, and the appointment of *cordons sanitaires*, rest with the Minister of War, the provincial magistracy have chiefly to attend to the epidemics which may visit their districts. They are enjoined to take all necessary measures to stifle epidemics at their birth, or at least to prevent their spread.

In every province of the hereditary states of Austria there is a medical man, charged with the supreme direction of sanitary arrangements. This is the *Landschafts-Proto-Medicus*, who is also a member of the council of state (*Sanitätsrath*), with a deliberative voice in the provincial assemblies.

The director of medical studies in the University of Vienna is also the *Proto-Medicus* of the empire. His circle of activity is therefore, as may be conceived, extremely wide, for it comprehends the whole sanitary organization throughout every part of the Austrian monarchy. This officer is second only to the Chancellor, with whom he maintains close relations,—the latter demanding his advice on all arrangements connected with the public health. The appointment of the *Proto-Medici* of the provinces is in the hands of the Emperor; their salary is usually 1000 florins (about 100*l.* per ann.)

Every provincial government has a medical reporter attached to it, whose duty it

is to attend at the meetings of the magistracy, to vote on all questions as one of that body, and to assist in the periodical statements required at head quarters, touching—1, the health of the local population and of their domestic animals; 2, the hospitals, their management, and the treatment therein adopted; 3, the apothecaries' shops; and 4, the conduct of the medical men who are in the service of government.

The provincial magistrates have the charge of the public health in their respective localities, and to them the district medical officers direct their reports on all such subjects; for example, as the rise and progress of epidemics, &c. On every occasion of adopting any new sanitary arrangement, they are obliged to take the opinions of the medical faculty of the province.

The district medical officers (*Kreis-physiker*) are appointed by the provincial authorities, with the consent of the *Proto-Medicus* of the province; and finally the government sanctions the appointment, if not otherwise advised.

In those towns which possess a university or a lyceum, the *Proto-Medici* are also directors of medical studies, presidents of the faculty, or the College of Physicians. But Vienna is excepted from this arrangement; there the *Proto-Medicus* of Lower Austria only exercises his jurisdiction beyond the capital. Those universities also are excepted which, like that of Pesth, possess at the same time a Director and a *Proto-Medicus*.

One part of the duties of the *Proto-Medici* is to exercise a political censorship on all works and articles in the journals connected with medicine: the authors are obliged to send their manuscripts to these officers previous to publication. Wherever there are both a *Proto-Medicus* and a *Director* in any city or town, it is the latter who acts as censor.

Among the other functions belonging to the *Proto-Medici*, are—1, that of having an eye upon the different orders of practitioners, such as the oculists, dentists, apothecaries, and midwives, throughout the province; and, 2, that of superintending the hospitals, asylums, and prisons. Their qualifications for the post must comprehend an exact knowledge of the nature of the country, its inhabitants, and their habits of life—all with reference to the public health. He must offer suggestions to the government from time to time relative to the means of removing or destroying injurious influences; and his special duties embrace the noticing of every thing connected with ill judged sites for building, the presence of marshes, bad water, the popular prejudices respecting

the physical education of children, &c. He must also see that there is a sufficient supply of clever medical practitioners in each district, and that they be not too far asunder. Quacks, and charlatan practitioners of every sort, male and female, who have not duly qualified themselves by passing the proper ordeals, he is authorized to put down; and he must take care that nobody sell drugs except the regular apothecary, and that the latter offer for sale no emmenagogues, violent medicines, or poisons, unless when applied for through the recipe of a regular physician or surgeon. He has also to inspect the foundling and maternity hospitals.

On the occurrence of an epidemic, he must repair to the place, and take measures with the district practitioners for its subdual; and when it is over, he must draw up a full report of the circumstances of its rise, progress, nature, symptoms, &c. with such pathological and therapeutical observations as seem to be called for. The *pharmaciens*, and their establishments, are under his strict surveillance; with the injunction, that on the proper discharge of this duty, depends the safety of the subject from the pernicious consequences of bad drugs. When obliged to travel in the performance of his functions, he is paid his expenses and an indemnity. At the end of every year he is bound to send in a report to the government of the province, stating the general sanitary history of the annual period just elapsed: to this he adds a list of the births, marriages, and deaths, and of the numbers received into the hospitals, asylums, &c. with returns of the number cured, or who have died. He appends likewise an account of the atmospheric constitution of the year, and of all the phenomena which seem to affect the health of man and domestic animals: besides all the remarkable cases which have connexion with the province of medicine and surgery. All this is founded on the reports of the subordinate medical officers who have charge of the several districts.

The *Proto-Medicus* of a maritime province is by right a member of the sanitary council of that province, if he reside in the district.

The *Proto-Medicus* of Lower Austria has a most extensive range of duties. Among others, he visits once a month, and without previous notice, all the hospitals within his jurisdiction, including the lunatic asylum, &c.; and the results of his examination are transmitted to government. At the end of every year, he appends to his report a list of all the practitioners within his district, with their names, appointments, and the universities where they studied.

With regard to the great body of medi-

eal practitioners, it may be divided into the several classes of the town physicians (*stadtphysiker*), the circle and district physicians and surgeons, the midwives, and the veterinary practitioners, who have been only of late recognized. The arrangement of the profession, which has long subsisted under this monarchy, has been to keep in government-pay a sufficient number of town and circle practitioners. Formerly there were, for example, nine medical men charged with sanitary affairs in Upper Austria, north of the Enns; but latterly there are, instead, a physician and surgeon to every circle, with two district practitioners. In Lower Austria, in like manner, there are in every circle a physician and a surgeon, with four subordinate practitioners, all salaried by government. The Emperor keeps the nomination to the chief places in his own hands, but always pays due attention to the recommendation of the local governments. When the situation of surgeon to a circle is vacant, the chancellor at Vienna is immediately apprized of it; and the first offer of the place is made to those surgeons who have been educated at the Institute of the University of Vienna. It is announced in the Vienna Gazette, that those surgeons who would have the appointment should send in their claims to the chancellor, and not till no surgeon of this class is found forthcoming, is the place offered to others.

The appointments of circle physician or surgeon, are only bestowed on those who have obtained a diploma in midwifery; for, in places distant from the capital, the circle physicians are charged with the examination of the midwives, conjointly with the circle surgeons, who are obliged to give them instructions. Both officers are obliged to shew that they have made a special study of legal medicine, medical police, and veterinary medicine, and that they are familiar with the language of the country.

A preference is generally given, in these appointments, to those military surgeons who have served, and also have shewn themselves experienced in civil practice; and, in every instance, the utmost attention is paid to the diligence, devotedness, and moral conduct of the candidate.

Throughout the whole of the Austrian states, it is the almost invariable practice to give no appointment, especially of a medical nature, to any one not born in the country, and who have not studied at some national university. When, in fact, a place is vacant, the names of three native graduate candidates are to be submitted to the Emperor.

It is a repeated injunction in the ordinances, never to give the appointment of a

physician to any one who has not served many years in a large hospital. Recently a law to that effect has been made; and in order to ensure its observance, it is customary, on the occurrence of a vacancy, to advertise it in the Vienna Gazette for several days previous to the final nomination by the court.

It is a strong recommendation to a candidate, that he shall have contributed articles to the "*Medical Annals of Austria*;" the titles of these articles must be set forth, and if they relate to epidemic or endemic diseases, to remarkable cases in pathology, to medical topography—or contain suggestions for the preservation or amelioration of the public health—they are the more favourably looked upon. The careful and successful practice of vaccination, *gratis*, on a great number of poor children, is also a passport to preferment.

Residence within their respective circles is strictly enjoined to the *Kreisphysiker*, and they are forbidden, under the penalty of being deprived of their offices, to change their place of abode without due notice of their so doing.

In consequence of a notification to government, that in several of the provincial towns the *Physici* accepted senatorial dignities, and mairies, to the neglect of their other duties, an order has been issued denouncing the practice, and enjoining an undivided attention to their proper functions.

Several appointments, with salaries of 600 florins (60*l.*) per annum, have been recently made for veterinary practitioners in the German provinces of the empire; and the preference, in selecting the persons to be so endowed, is always given to those who have studied veterinary medicine at Vienna. Their residence is also assigned them by the government*.

ST. BARTHOLOMEW'S HOSPITAL.

Compound Fracture of the Leg—Dangerous Hæmorrhage—Ligature—Amputation.

JOHN BOW, æt. 53, a bricklayer's labourer, was admitted into this hospital on Thursday, October 30th, with a compound and comminuted fracture of the tibia and fibula. The accident occurred in the following manner:—He was climbing up a ladder, when his foot slipped and he fell from a height of six feet, with his right leg under him. At the time of his admis-

* For the above article we are indebted to the *Observateur Medical Belge*; a monthly periodical recently started in Brussels.—E. G.

sion there was much hæmorrhage from the wound; and this continuing, it was thought proper to send for Mr. Earle. When this gentleman arrived, the bleeding was not so profuse; and on examination, he deemed it necessary to remove three portions of the fractured bone. The largest of the pieces taken away was about three inches in length, and in breadth it comprised about one-third of the middle of the tibia. Its upper extremity was sharp and pointed; its sides and lower end were rough; the other pieces were small and irregular in shape. The anterior tibial artery was bare to the extent of an inch, and the posterior tibial could be detected on the introduction of the finger: both pulsated freely, and the pulsation could be likewise detected below the injury. The man, after this day, went on pretty well. Purgatives and enemias were given to remove costiveness; liq. opii sedativus was administered to procure sleep.

On the 2d November, symptoms of pyrexia coming on, the patient was directed to take liq. antim. tart. with saline mixture; and on the 6th, pain of the chest and cough being the subject of complaint, a blister was applied over the sternum. The hæmorrhage continued, but daily diminished in quantity.

On Sunday, the 9th inst. at 11 o'clock A.M. blood was discovered to be rapidly pumping out from the back part of the wound. Luckily a gentleman arrived at this moment, and speedily stopped the hæmorrhage by pressing the femoral artery against the pubis. The man had, however, lost a quart of blood; his pulse was sinking rapidly; a tourniquet was applied, and brandy administered. Mr. Skey having been sent for, arrived in a few minutes, and concluding, from the direction of the wound, &c. that the posterior tibial artery was injured, ordered the man to be removed to the theatre.

Mr. Skey then commenced by enlarging the wound, to the extent of an inch, in a direction upwards and backwards, and then cutting down between the soleus and deep-seated muscles, found the vessels at the back of the wound. Suppuration had taken place extensively in the neighbourhood of the vessels, and had separated them from their connexion with the deep muscles: their relations to each other were likewise altered; the nerve lying internal and anterior to the artery. The tourniquet being loosened, the vessel was seen pouring out its contents; it was secured by a ligature, and, as there was much venous hæmorrhage, a branch of the saphena vein was lightly tied. The pulse being reported small and irregular, and the surface of the body covered with a

clammy perspiration, Mr. S. thought it right to have the patient removed. The lower end of the wounded vessel was not tied, and, in expressing his reasons for this omission, Mr. Skey said, that from having seen the inner coat of the upper portion of vessel, he was led to believe that the other end had retracted; that as bleeding had not yet occurred from that extremity, and the force of the circulation was diminished, it was fair to infer that hæmorrhage would not occur from it: he, however, directed the tourniquet to be kept ready, and the patient to be watched during the day and night. Another reason which influenced his decision was, that had he detained the man much longer on the table, unpleasant consequences might have ensued.

November 10th.—The patient passed a tolerable night, and his pulse rose under the effect of stimuli.

11th.—Considerably worse; pulse quick and intermitting; great anxiety and restlessness.

On Wednesday, the 12th, the limb was removed by Mr. Earle; since then the patient has been slowly improving, but is still in a precarious state.

Examination of the Limb.—The ligature was found above a longitudinal fissure; the inferior portion being bound down by lymph, and covered by the nerve, led to the belief of the vessel's not being continuous. The muscle was likewise found divided at the same point as the wound in the artery.

SURGICAL REPORTS

FROM THE

LONDON DISPENSARY.

By R. R. ROBINSON, Esq.

Surgeon to that Institution.

CASE I.—*Malignant Ulceration of the Hand—Amputation of the Fore-arm—Secondary Hæmorrhage—Return of the Disease in the Stump and on the Scalp.*

SARAH HARRIS, æt. 55, admitted November 25th. First perceived a small tumor over the index metacarpal bone of the right hand three years and a half ago, attended with a burning pain, which gradually increased in size, and ulcerated. She had it cut out; there was much bleeding after the operation; some vessels were secured by ligature, one of which gave way, and in consequence a large quantity of blood was again lost. About

three weeks after the wound had completely healed, the tumor reappeared, and she again experienced the same burning pain. In August she put herself under the care of a quack, who applied irritating applications, by which the pain and tumor were much increased.

There is now a foul malignant fungous ulcer, with hard and ragged edges, about two inches and a half long, and rather more than one broad, situated over the anterior part of the metacarpal bone of the right index finger, extending towards the thumb, where it is more tender than elsewhere; there is occasionally a little bleeding; the surrounding skin is red and inflamed, the inflammation extending towards the back of the hand; there is excruciating pain (day and night, preventing sleep) in the ulcer, but it does not extend up the arm. There is no affection of the axillary glands or mammae; the catamenia are now regular, and have been so throughout. Low-spirited; bowels open; pulse regular, but feeble.

Uniform pressure. Solut. Calcis Chlorid. $\mathfrak{z}\text{ij}$.; Aq. Puræ, $\mathfrak{z}\text{vi}$.; Tr. Opii. $\mathfrak{z}\text{i}$. pro lotione; Pulv. Doveri, gr. x. o. n.; Inf. Gent. Co. $\mathfrak{z}\text{iss}$. ter die.

Nov. 27th.—Pain very great, more particularly towards the inside of the thumb, where there seems a small tumor forming; discharge from the ulcer very offensive; pulse 120. The pressure continued, and a solution of opium, $\mathfrak{z}\text{j}$. to a pint, substituted for the lotion.

Dec. 3rd.—Pressure has been regularly applied until to day; sore much the same in appearance—less offensive—surface sloughing—pain agonizing, always worse at night; seldom obtains sleep.

Omit the pressure. Rep. Pil. et Med.

9th.—The wound continuing sloughing, and the pain very severe, though rather less since the pressure has been removed, by her express desire, and with my friend Mr. Luke's sanction and able assistance, I removed the fore-arm high up, by double flap; several vessels were secured, and the stump dressed with ligatures and strapping. The operation was well born.

10th.—Thirty drops of laudanum were given immediately after the operation, ten in the course of the afternoon, and thirty again at night. Has dozed frequently; skin freely perspires; pulse 108; tongue clean and moist; some oozing from the stump; a slight cough; bowels confined.

M. S. c. Rho. statim Mist., Salin. quartis horis; Lotio frigida.

11th.—Some sleep from an opiate, but altogether a restless night; a little bleeding; bandage tight. Upon taking off the dressings, there were seen some vesicles and livid spots at the edge of the stump, and numerous coagula in the interior; upon the removal of which a small artery was observed bleeding. Between the bones which was secured by ligature, pieces of lint were inserted into the stump; a strip or two of plaister brought the edges together, and a bread-and-water poultice was applied.

20th.—The stump suppurating well; no further bleeding; all the ligatures have come away; a small ring of the radius and ulna black; less pain. Stump dressed to-day.

Feb. 25th.—The stump has been healed some time, all but a small spot over the ends of the bones, from whence a small piece of bone has already come, and two others are coming away; improved much in health at one time—not so well now; countenance looks haggard and sallow; nights are very restless; she has had a cough and dyspnoea some days, to which she is subject every winter, which has been relieved by blistering, opium, squills, and aloes. A few days ago she perceived a small pimple over the upper part of the left side of the frontal bone, apparently attached to the occipito-frontalis muscle; it is very tender to the touch, particularly since she scratched it, two days ago. Tongue coated and white.

Cat. panis. Tr. Opii. $\mathfrak{m}\text{xxx}$. o. n.; Mist. Cath. p. r. n.

March 9th.—The tubercles on the forehead have spread slowly; there is another close to them, not at present painful. Two small tubercles, that seem disposed to fungate, at the outer side of the stump, which burn at night, but are cooled by goulard wash.

Opii, gr. i.; Scillæ P. gr. i.; Aloes, gr. ij . o. n.

23rd.—Pain has been very great, particularly in the stump; looks more haggard and sallow; orthopnoea, a sensation as if a load was attached to the lungs, preventing her from raising them; cough continues; the pleses on the forehead and stump much the same; pain, apparently of a rheumatic character, down the left side of the face and neck; has taken colicium, without relief; tongue white, moist; pulse feeble, quick, and irritable; bowels open.

Lin. Volatile Opiat.; Quin. Sulph. gr. i.; Ext. Conci, gr. x. ter die.

April 5th.—Weaker; more sallow; breathing short and wheezing; much

expectoration; is reported to have brought up some black and green fluid, with some blood, a few days ago; the tubercles about the forehead and stump on the increase; no rest without thirty drops of laudanum at bed-time; pulse 104; tongue moist.

11th.—She was seized with pain at the epigastrium, nausea, and distention of the abdomen; the dyspnœa increased; she was light-headed; had lividity of countenance, lips, and nails; and died this day.

I could not obtain permission to examine either the stump or the body. The hand is in my possession; I have injected it with size and vermilion. The tumor seems to originate from the theca of the flexor tendon: at its base it is hard, and apparently scirrhus; above, it possesses the characters of the medullary fungus; it is softening in the centre, where it is of a red colour—elsewhere it is brown; there are no vessels observable in the tumor, though a branch well filled runs by the side of it.

REMARKS.—The reappearance of the disease in the cicatrix three weeks after the healing of the wound, its appearance in the scalp, and *subsequently* in the stump after amputation, and the sallow, haggard appearance of the countenance, show that in this case the constitution was much affected, if the disease was not of constitutional origin. I very much regret I could not obtain a post-mortem examination, for I think this patient died chiefly from disease of the lungs; but whether the pulmonary affection was malignant, or simply chronic bronchitis, or both, is not clear. The sense of a load attached to the lungs, which prevented her raising them, (to use her own words), the appearance of tubercles in the wound, the stump, and the scalp, would induce the suspicion that malignant tubercles might have been deposited in the lungs also; more especially as it is not uncommon to find such deposition in malignant diseases: on the contrary, the absence of dulness at any particular part of the thorax, the apparent patency of the pulmonary tissue at most points, and the decided wheezing throughout, are more in favour of the existence of bronchitis, and *no* other pulmonary affection.

This is a case where the chances were against a successful result, and therefore no one would, I think, have *proposed* amputation; but when the patient, from extreme suffering, urged its performance, I considered myself justified in complying. I think it very *doubtful* whether she would have existed four months without the operation; and it is *certain* that she had, during a great part of that time, more ease

than she had for a long time previously experienced.

It is further worthy of notice, that secondary hæmorrhage followed both operations to which she submitted.

CASE II.—*Malignant Ulceration (?) of the Right Groin—Fatal Hamorrhage.*

Mary Glyn, æt. 60, a thin, emaciated, sallow woman, admitted September 12th, perceived a small pimple over the symphysis pubis, many months ago, which she neglected. It has since spread considerably; there is now an ulcer extending from the symphysis throughout the right groin to the anterior superior spinous process of the right ilium; the ulcer, in appearance, is much like some forms of chimney sweepers' cancer (she has not, however, been in the way of soot): the edges are irregular, hard, thick, and everted; in the centre the ulceration is very deep, and covered by a thin yellow slough-like looking substance. Pain excruciating; no rest; no appetite; pulse feeble and quick; tongue clean; great prostration of strength.

Ol. Ricini, ʒi.; Ung. Opii. (she refused to poultice the ulcer); Inf. Gent. Co. ʒiiss. M. S. ʒi. ter die.

Sept. 16th.—Ulcer cleaner—it suppurates freely; pain considerable; excavation does not look quite so deep. Having no person to take care of her, and being destitute of the necessaries of life, I advised her to go to a hospital, but she obstinately refused.

Rep. Ung. et Mist.

17th.—Last evening she suddenly felt wet, looked down, and found herself deluged with blood, which her daughter says was of dark colour, and came out in a stream, with great rapidity, in a quantity more than sufficient to fill two wash-hand basins; in five minutes she was a corpse. A post-mortem examination of the body was refused; but I carefully examined the wound, when I found the superficial fascia and portions of the fascia lata destroyed, as well as the vena saphena major. I think that the ulceration had also destroyed a portion of the right femoral artery and vein, as neither of these were discoverable; but in the place where they should be, there was an irregularly ulcerated cavity, of chocolate colour, extending some way towards the spine of the ilium, in which was some chocolate coloured fluid, more like that which comes from a softened medullary fungus, than actual venous blood.

REMARKS.—I very much regret that I could not obtain a post-mortem examina-

tion here, as I think it would have been both interesting and important.

The feature of most interest in the case, was the sudden and fatal hæmorrhage—an occurrence, as far as I can see, unavoidable; for it did not appear to me justifiable to apply a ligature upon the artery above the ulcer before any bleeding occurred, for the following reasons:—

1st, Because, in many instances of extensive ulcers over large vessels, they have not been involved, and no hæmorrhage has ensued.

2dly, Because, in some cases of this description, the vessels have been found obliterated at these parts.

3dly, Because the disease, having the appearance of a malignant one, it would in all probability have soon proved fatal, had the operation been successfully performed, and no bleeding ensued.

4thly, Because the ulcer, being placed over the femoral artery and vein, might have perforated the latter and not the former; and then an extensive and perhaps fatal hæmorrhage would have supervened, notwithstanding the operation. When the bleeding did occur, the blood was so rapidly and so largely poured out, and the artery and vein appeared so much diseased, that surgical aid (even had she gone, as I wished her, into the hospital), would, I apprehend, have been in vain.

CASE III.—Malignant Ulceration of the Neck of the Uterus—Communication between the Bladder and Vagina.

Mary Clark, æt. 42, admitted March 16th. The mother of nine children; the youngest $6\frac{1}{2}$ years old. All her labours natural. In June last she experienced, for the first time, sharp pains down the inside of both thighs, which lasted six hours, and then removed towards the anus, where they remained for the same length of time, and then for six hours were seated in the vagina: the remaining six hours out of the twenty-four she was easy. This state has continued daily, with now and then an interval of two or three days, ever since. About the time that she first felt the pain, the catamenia came on excessively, and lasted for a fortnight. They have since returned, in greater or less degree, weekly. Sometimes they are very deeply tinged with blood, at others they are pale. She is always easiest at this period. Upon examination through the vagina, the os uteri was found to be hard, ulcerated, and occupied with a cauliflower-like excrescence, the discharge from which is of a red colour, and free from fætor. Fallen away for the last four months—the two last rapidly. She is now exceedingly reduced; features very much shrunk;

countenance sallow; appetite gone; bowels open.

Solut. Calcis. Chrolid. Tr. Opii, aa. $\mathfrak{m}\mathfrak{x}$. ter die.

May 17th.—Continued the mixture a month without any alteration; more feeble, thin and sallow; pains at times shooting and severe. From constant straining, piles were produced a week ago. A constant bloody discharge from the vagina, with some clots.

Omittatur Mist. Pulv. Opii, gr. ij. o. n.

June 7th.—The opium constipating the bowels, hyoscyamus was substituted for it; but it griped and irritated the bowels so much that the liq. opii sedativ. was substituted for that: this agreed well; the pains subsided under its use, and she seemed much better until a week ago, when she was frightened by a boy falling out of a window, since which she has had more darting pains about the pubes, rectum, and back; more bloody discharge from the ulcer, which, to the touch, is much the same; more bearing down, and more difficulty in making water. Countenance is more leaden; pulse small, soft, and feeble; but the tongue remarkably clean and moist.

Repetatur Pulv. Opii.

18th.—Less darting pains in vagina; less discharge; suffers much from flying pains in the upper, and also in the lower extremities.

September 13th.—Has sunk greatly the last few days; cannot sit up; the legs swell; less pain in the vagina; some clots of blood weekly discharged from there; sometimes slight retention, at others involuntary discharge, of urine.

Ol. Ricini. Rep. Pulv.

15th.—Urine was retained till this morning, producing great distress, when she had a copious discharge from the bowels, with hard lumps, soon after which a large flow of urine took place, and she is now wonderfully relieved.

Repetantur Pil. et Ol.

21st.—Quite easy; has not passed urine, and she distinctly states that she has had no involuntary flow. Intestines tympanitic.

24th.—No urine passed since last report. She was exhausted, and died this morning.

Dissection.—Complexion and skin generally sallow; no fat under the integuments; some ounces of serous fluid in each side of the thorax; lungs unadherent, œdematous, particularly posteriorly; heart healthy. A considerable quantity of serum in the abdomen; a great part of

the peritoneal coat of the liver thickened, puckered, and cartilaginous; stomach large, and greatly distended with gas, as were also the small intestines and transverse colon; the structure of these viscera healthy; mucous membrane of the rectum slightly thickened, and of a deep red colour—in some parts almost black, free from ulceration. The uterus was puckered about the neck, which was the seat of a medullary ulcerated fungus, involving and destroying the surrounding parts. Several portions of fungus, some of white, others of deep red colour, sprung from the vagina, the neck of the uterus, and under surface of the bladder, of the consistence of brain, softening under pressure between the finger and thumb. The ulceration had extended completely through the neck of the uterus, so that the reflection of the peritoneal coat was all that prevented the body of the uterus from being completely separated from the cervix during life; this was so softened by the disease, that the slightest touch made a rent in it. The body of the uterus was striated, hard, and apparently scirrhus; in its interior there was a layer of a yellow substance resembling fibrine. The lateral ligaments of the uterus were of cartilaginous hardness; the ovaries small, and of deep purple colour.

Bladder empty: on opening it, the orifice of the urethra was of a highly red colour, from increased vascularity: upon cutting it open entirely, it was found to have a very extensive communication with the vagina, having been implicated in the ulceration above described.

Lumbar glands unaffected.

REMARKS.—This case is important, as bearing upon the question of excising the neck of the uterus in cases of malignant disease; and proves the necessity of operating early, if we operate at all, as the ulceration here had extended into the bladder, and extensively destroyed its arteries. This extension of the disease appears no uncommon circumstance, for I have in my possession two other preparations illustrative of it.

It is most probable that the existence of this communication might be ascertained by passing a catheter into the bladder, and examining with the finger per vaginam; though I am not certain that this method might not deceive: if the catheter is touched by the finger so introduced, then the communication would be obvious; but if it is not, it is not so obvious that no communication exists, for the extension and irregular growth of the fungus might sometimes have a valvular effect, and sometimes not; and thus I

would explain the circumstance of there being at one time incontinence, at another retention of urine.

If the woman's account of her sufferings can be relied upon (and she was very clear in what she stated), there was little or no urine secreted for nine days prior to dissolution, and the pain shifted, at the commencement of her illness, no less than *three times in every twenty-four hours, lasting exactly six hours in one part.*

It is also worthy of note, that, with such extensive malignant disease of the uterus, the lumbar glands were unaffected.

With these cases I shall conclude my Surgical Reports, as I fear I have already trespassed too much on the pages of this journal. When it is stated that the preceding cases, with very few exceptions, occurred within a period of twelve months—viz. from October 1832, to October 1832—it will, I think, be admitted that Dispensary practice is capable of furnishing instruction to pupils, and facts worthy of a place among the records of our profession.

STATISTICAL SOCIETY.

Monday, Nov. 17, 1834.

THE MARQUIS OF LANSDOWNE, PRESIDENT, IN THE CHAIR.

THE Society held its first ordinary meeting for the season on Monday evening, when about 150 of the Fellows attended. The business commenced by reading over the names of all those who were elected Fellows since the anniversary meeting, as well as a considerable list of donors who have presented books, maps, &c. to the Society.

An account of the proceedings of the Statistical Section of the British Association, lately assembled at Edinburgh, by Mr. Maclean, was read by his brother secretary, Mr. Woronzow Greig; after which a paper by the latter gentleman was communicated to the Society, and excited much interest. It related to the *character and condition of the Irish labourer.* Mr. Greig made a tour through the sister country last autumn, for the express purpose of ascertaining the actual state of the peasantry, and of agricultural labour. His account of both is very unfavourable: he estimates at a very low rate the amount of labour produced, or capable of being produced, by the common Irish operative: the fact he attributes to the habits of indolence of the natives, and their contentedness with a most meagre and insufficient diet. Their love for ardent spirits, too—

to which they are most deplorably addicted in the absence of any more wholesome stimulant—is ruinous both to their health, strength, and prospects.

The last communication read to the meeting, was an interesting account of the state of the savings banks of Exeter and Devon.

Among the Fellows who were present, we noticed Mr. Malthus, Mr. Hallam, and several other distinguished persons.

PAUPERS AND PARISH SURGEONS.

NOTE FROM MR. HOOPER.

To the Editor of the Medical Gazette.

SIR,

PRESUMING the observations in the last two numbers of your Gazette, upon the want of promptitude in parish surgeons, relate to the case of a child who was burnt to death in my parish, and consequently under my care, I feel myself called upon to correct the very erroneous statements there put forth, although you have done me the justice to acquit me of all blame in the case. The newspaper report of the coroner's inquest was an exaggerated statement of the facts, because I suppose the reporter thought the truth too insipid to answer his purpose; but even that report would not warrant your assertions, that "a poor child was lost for want of timely medical assistance," and that "some hours were lost before a little liniment could be procured for the burnt sufferer through the necessary order, and several more elapsed before the surgeon could attend in person; but when he did arrive, it was too late—the patient was dead!"—No. 363, p. 241.

Now, sir, if you will take the trouble to refer to the coroner's notes, you will find that three of the most respectable witnesses swore that my assistant attended immediately after the accident, and sent medicines as soon as he returned home from visiting it; which did not exceed six minutes; that no order was asked for, or required, by me or any of my establishment; that I attended the child twice the same day; that she was subsequently attended by another surgeon, at the request of her friends; and that she lived three days after the accident! I do not believe, sir, that these inaccuracies were published intentionally; at the same time I feel that due caution has not been observed by you, in promulgating such reports without good authority, and as they are calculated to injure my character, I trust you will do

me the justice to insert this letter in your next number.—I am, sir,

Your obedient servant,

R. L. HOOPER.

London Road, Southwark,
Nov. 18, 1834.

[As Mr. Hooper has thought fit to come forward and connect his name with the transaction to which we alluded, we have only to regret that he did not shew an equal zeal in correcting the misstatements of the newspapers. We had no access to the "coroner's notes," but were simply indebted to the public prints for our information. One word more: if Mr. H. had read our remarks, with but a common understanding of them, he would not have fallen into the gross mistake of supposing that we complained of any "want of promptitude in parish surgeons;" much less that we had the most remote intention of "injuring his character."—ED. GAZ.]

SATURNINE AMAUROSIS.

IN a memoir on this subject recently published by M. Duplay, of the Hôpital de la Pitié, attention is directed to the following propositions:—

1st. Amaurosis, succeeding to colic from lead, or to the nervous colic that approaches it, presents this characteristic, viz., that it shews itself suddenly; in some hours the patient completely loses the power of vision, and can no longer distinguish the light.

2nd. It commonly makes its appearance after several attacks of colic; yet it may supervene on the first attack, as well as many other lesions of innervation in some individuals affected with lead colic.

3rd. Most commonly the disease is announced by the following symptoms; cramps; pains in the arms; some paralysis of the wrist; epileptiform fits and delirium; occasionally, on the contrary, it comes on suddenly, and it is only after some time the other symptoms make their appearance.

4th. The duration of this form of amaurosis is commonly short; some hours to one or two months; the mean term is five or six days: in one single case from lead colic it had resisted all the means employed. It has shewn the same tenacity in another case, observed by Felix Plater, in which the amaurosis coincided with an hysterical colic. Stoll says, that amaurosis from lead, or hysterical colic, is temporary, and disappears on the cessation of the paroxysm.

5th. The same treatment as for lead colic generally dissipates the amaurosis: in one case, large bleedings were inefficient,

and purgatives have removed it in another, where it was complicated with nervous colic and constipation.—*Archives Generales, and Dublin Journal.*

PINEAL GLAND.

M. WÜRZER, the venerable professor at Marburg, has recently analysed the gritty matter found in the pineal gland, and has ascertained it to consist of carbonate of lime, phosphate of lime, iron, and manganese. Fourcroy and Vauquelin could never obtain from it more than phosphate of lime and animal matter; but M. Würzer, having frequently repeated his analysis, is positive as to the results.—*L'Observateur Medical Belge.*

ANATOMICAL DIFFICULTIES OF THE SEASON.

Owing to the absurd prejudices which still exist among many of our parish functionaries, much difficulty has been felt in procuring any thing like a compliance with the ninth section of the anatomy act this season. There is said to be no considerable mortality just now; but such as there is, perhaps might afford a reasonable supply to the schools, were there no obstacles thrown in the way by certain ill-judging overseers and ultra-humane vestrymen. A communication from Lord Duncannon, to the parish of St. Mary, Whitechapel, exhorting the authorities in that quarter to second the exertions of the Inspector of Anatomy, was reluctantly listened to on Thursday, and a tardy consent given to attend to his Lordship's suggestions.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES ON THURSDAY, NOV. 20, 1834.

Isaac Byerley, Liverpool.
George Varah, Sheffield.
Frederick James Chapple, Stonehouse, Devon.
Charles Redwood Vachell, Cardiff.
James Berry, Bristol.
James Newton Heale, Bristol.
Jabez Carr, Birmingham.
William Jones, Birmingham.
James Taylor, Birmingham.

NEW MEDICAL WORKS.

A Treatise on the Nature of Cholera, by S. Brougham. Post 8vo. 5s. 6d. cloth.

Elements of Chemistry, by E. Turner. Fifth edition, 8vo. 21s. bds.

The Principles of Ophthalmic Surgery, by John Walker, of Manchester. 12mo. 5s. 6d. cloth.

Good's Study of Medicine, fourth edition, by Samuel Cooper. 4 vols. 8vo. 3l. 3s. bds.

Popular View of Homœopathy, by the Rev. Thomas Everest. 18mo. 3s. 6d. bds.

Treatise on the Diseases of the Eye, by William Mackenzie. Second edition, 8vo. 25s. bds.

Sir A. Cooper's Lectures on Surgery. 18mo. Fourth edition, 6s. 6d. bds.

The Medical Pocket-Book, 1835. 3s. cloth, 5s. tuck.

Mr. Curtis has in the press a new edition of his Treatise on the Physiology and Diseases of the Eye.

NOTICES.

"J. G." on the treatment of Jaundice is neither original, nor sufficiently practical for us.

We can make nothing of the paper on Epilepsy, by L. H.: it reminds us of some of the quack advertisements which are but too often to be met with in the newspapers.

"A Parishioner of St. Pancras" is requested to look into some of our back numbers, and see if we have not already done justice to the excellent and charitable institution alluded to.

"A Professional Man" (Hull) will have perceived ere this time that he did us injustice:—the second part of his letter is unintelligible to us.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE IX.

DISEASES OF THE AERIAN PASSAGES.

CROUP.

So far, gentlemen, under the name of catarrh, we have spoken of the inflammations of the aerian mucous membrane, which have for their results the secretion of a fluid which remains in the liquid state. We now proceed to the description of another species of inflammation, which also has for its result a fluid secretion, but this secretion almost instantly concretes, and forms a false membrane, lining the affected parts of the air-tubes. This is called *Plastic Inflammation*, or, more commonly, *Croup*.

History.—The nature of this disease seems to have been unknown to the ancients. In all probability, however, it existed in their times, but as most of its signs are common to other pulmonary affections, especially catarrhs, and as morbid anatomy was then totally unknown, it is very possible that its special nature was either overlooked or misunderstood. The first author who mentions or throws any light on the subject, seems to have been Baillon, or, as he is often called, Ballonius—the French Hippocrates; he described something similar to it in the year 1576. Tulpius, Morgagni, and others, had some notion of the disease, inasmuch as they mention excretions of *polypi*. Some

thought the mucous membrane itself was thrown up, and others that the blood-vessels of the lungs were separated and expectorated. Ghisi, of Cremona, in 1740, first described the true character of the affection, and after him many authors took up the subject, more particularly Dr. Home, of Edinburgh; finally, Bretonneau, of Tours, has given the most complete account of Croup, under the name of “*Diphtherite*.”

Morbid Anatomy.—Croup consists in an inflammation of the mucous membrane of the aerian passages, having for its consequence a secretion which concretes almost as soon as it forms. I present you specimens of these concretions before I proceed farther. [Four beautiful specimens of the disease were then exhibited.]

When you elevate the concretion or false membrane, you will perceive that the mucous surface beneath is reddened and swollen, but rarely to the degree we find in catarrhs; we must therefore conclude that the pseudo-membrane is not caused by a greater intensity, but that it rather depends upon some specific nature, of the inflammation. It has been supposed that catarrhs result from inflammation of the secreting follicles of the mucous membrane, and croup of the capillary arteries of its tissue. This opinion is plausible and probably correct, but it has not yet been proved.

The false membrane lines and moulds itself to the part inflamed, and extends no farther; its thickness is from half a line to a line, and is generally greatest at its upper extremity; its colour is white, or whitish-brown; it has the consistence of boiled white of egg, and its firmness is always greatest where it is thickest. As it descends into the trachea it becomes thinner and softer, terminating in mere mucus. The secretion constantly forming from the inflamed parts, separates the false membrane from the mucous surfaces, particularly at its inferior and soft extremity, and

then, white shreds are often expectorated; the new secretion concreting in its turn.

The disease may attack any part of the acrian passages, as has been distinctly shewn by Bretonneau; thus it may affect the cavities of the nose, the pharynx and mouth, the epiglottis, larynx, trachea, and the bronchial tubes; nay, the pseudo-membranes have been observed in the œsophagus, stomach, and intestines: with the exception of the nares, I have seen it in all these parts.

Croup attacks the larynx most frequently: Laennec observes that it rarely extends above the glottis; but, gentlemen, nearly every preparation before you, and there are six, presents the false membrane, also on the inner surface of the epiglottis; there can be no question, however, but that the disease is usually confined to the larynx and epiglottis, and the adventitious formation then takes the characters I have already described.

But when the croupal membrane extends into the bronchial tubes, it then becomes modified in its appearance; it generally is formed into a single cylinder, as Bretonneau has shewn us in this plate [shewing it], and occasionally into a series of tubes inclosed within each other in the closest contact, and forming altogether a solid body of a thick and tolerably firm structure, and of the exact form of the tube from whence it has been abstracted: upon making a transverse section of this polypiform substance, its concentric laminæ are very apparent. It adheres but slightly to the mucous surface, and may easily after death be drawn out entire. This structure was, I believe, first described by Dr. Withering. The specimen I now present to you, shews a complete mould of a large bronchial tube, and its minutest ramifications. You perceive also the concentric laminæ upon its section.

The croupal membrane has never been seen to consist of these distinct layers in the larynx and trachea, but in the bronchi only; the reason of this seems to me obvious. When the larynx and glottis are affected, the passage of the air is so obstructed that the disease soon terminates either fatally or otherwise, and before a second membrane has time to form and envelop the first. When also a cough takes place, the column of air ascending the trachea is of sufficient volume, and is projected with adequate force to tear away the loosened membrane, and occasion its expectoration: if, however, the formation takes place in a bronchial tube, even of large calibre, the danger is less imminent, the column of air passing through that tube during a cough is of less volume; and, finally, as the vessel fills with the concretion, no air passes at all, so that

there is sufficient time and repose for the pseudo-membranes successively to form and surround each other.

Bretonneau was the first to demonstrate that the state of the fauces, which is known under the names of angina gangrenosa, cynanche maligna, or gangrenous sore throat, depended, in the greater number of cases, upon plastic inflammation, and that the supposed gangrenous slough was nothing more than adventitious membrane. He proved this, by shewing that there was no loss of parts upon recovery, which there would have been, had there existed previous gangrene; by the disease descending into the larynx, and producing all the symptoms of croup; and, finally, by repeated dissections, showing the continuity of the membrane.

When the disease attacks the fauces, small yellowish grey spots appear, surrounded by the mucous membrane, highly and darkly reddened: these spots enlarge, coalesce, and form a continuous false membrane of the colour and consistence of the buffy coat of the blood, lining the throat, more or less, completely. I have seen it cover the posterior half of the tongue, so that its anterior part might be elevated by a probe in a membranous form: it rarely passes into the œsophagus, but frequently into the larynx, and suffocates the patient.

If this form of the disease terminates favourably, the false membrane then detaches itself; it is replaced by a thinner and less plastic exudation, altogether similar to catarrhal mucus. Sometimes the membrane does not separate, but appears to be gradually absorbed, becomes then less opaque and sufficiently transparent for the colour of the mucus membrane to be seen through it; finally, it entirely disappears. In the worst cases, the pseudo-membrane is soft and friable, like soft cheese.

It may be observed here, that the croupal membrane almost always originates in the larynx in children, and does not spread into the fauces, and is not accompanied by symptoms of gangrene; while, in adults, it commences in the fauces, and passes from thence into the larynx, and the symptoms then frequently are similar to those of gangrene.

The observations of Bretonneau would lead to the supposition that gangrene of the fauces never occurred, but there can be no doubt it occasionally happens, although much more rarely than the plastic inflammation; it is very probable that a combination of the two affections may occasionally take place, that is, a false membrane may form over a gangrenous surface. [Drawings and a preparation of a false membrane on the fauces were now shewn.]

Symptoms.—Functional.—When croup at-

tacks the larynx and trachea, the functional signs must have relation to the respiration and the voice.

The respiration is always impeded in proportion to the quantity of false membrane, by which the tube is rendered narrower, and consequently the column of air of less diameter. The edges of the circumference of the inferior extremity of the adventitious deposit being loose, mucous, and soft, frequently adhere to each other, so as to close up the tube, and require a strong effort of inspiration to overcome the temporary obstruction: I have seen a slight film of pseudo-membrane traversing the upper part of the larynx, suffocate an infant almost instantly. The dyspnoea becomes always great when the concretion separates, and if it be not quickly expectorated often destroys the patient immediately.

The disease usually commences with the symptoms of common catarrh, soon to be followed by a violent cough, which rapidly assumes the croupal character: this cough is occasioned by the irritation of the false membrane, and may be considered as an effort of nature to expel it, which is occasionally effected in the form of small whitish shreds.

The acts of inspiration, and of coughing, produce peculiar sounds; it seems as if the noises were formed and resounded in a brazen tube, having some analogy to the crowing of a cock. The voice, too, has a similar character: these sounds have been denominated, croupal inspiration, croupal cough, croupal voice.

If the disease attacks the bronchial tubes alone, and not the trachea and larynx (which is I believe a very rare occurrence), the dyspnoea will be in proportion to the size and number of tubes affected; the croupal voice, inspiration, and cough, will no longer be present, and the expectoration of the false membrane is the only means of distinguishing the disease. I have seen two instances in adults, where, after violent coughing, pieces of false membrane of the form of the bronchial tubes were expectorated, being no doubt the polypi or bronchial vessels of the ancient authors.

When croup affects primarily the fauces, the act of deglutition becomes difficult, and there will not be present either dyspnoea, cough, or the croupal sounds; but when it progresses and descends into the rima glottidis and larynx, then all the before-described symptoms will be superadded.

Local Signs.—These signs have not been sufficiently studied when croup exists in the larynx, trachea, or bronchi. The appearances I have described under the head of Morbid Anatomy, afford sufficient local indications when the disease attacks the fauces,

General Signs.—Croup is always accompanied by general disturbance of the functions of the body: in most cases the inflammatory sympathetic fever is acute and intense, and frequently combined with irregularities in the movements of the heart. In some instances, particularly in hospitals, or under the influence of certain epidemics, the general signs assume an asthenic character: thus, the pulse diminishes in frequency, and becomes exceedingly feeble, the skin of a dirty or earthy aspect, the breath fœtid, even when no gangrenous points are seen in the throat, and the prostration of the strength of the patient is extreme.

Causes.—*Individual.*—Croup by far most commonly attacks infants, but it sometimes occurs in adults, particularly when it commences in the fauces.

External.—It often appears as an epidemic, especially in places exposed to the north and north-east winds, particularly when they blow with violence, and for a long time. Laënnec suspected, from seeing the plastic membrane forming in different and remote parts of the body at the same time, that the disease depended upon some peculiar state of the fluids rather than of the solids. The asthenic form of croup occurs most frequently in hospitals. The question of its contagious nature is not so decided as to render it prudent to allow persons to expose themselves unnecessarily to the breath of croupal patients.

Diagnosis.—It is sometimes difficult to distinguish this disease from acute laryngitis, particularly in children: but croup rarely attacks adults, and on the contrary children seldom labour under acute laryngitis.

You have no diagnostic mark even in the sounds of the cough or respiration, for sometimes they are but slightly formed, and frequently they are very like those produced in whooping cough. The only pathognomonic sign is the expectoration of shreds of the false membrane.

Treatment.—Our indications of treatment are, to destroy the inflammatory action, and to cause the expulsion of the false membrane.

You will recollect, gentlemen, I have already observed that croup must not be regarded as an inflammation of a violent, but of a peculiar, nature; for the redness of the mucous membrane is usually less considerable than in ordinary catarrhs: you must consider, too, that the formation of the croupal membrane is probably an effort of nature to terminate the inflammation by such a secretion, as pus is the termination of that state when occurring in the subcutaneous cellular, and in other tissues; so that we have rather to contend here with its effects than with the

causes producing them. It is true that, although we may be certain that the false membrane exists, we cannot be sure that the inflammation producing it has subsided, consequently it will be prudent to bleed or apply leeches in proportion to the strength of the sufferer; but these means must not be carried to any considerable extent, as experience has distinctly shewn. The usual antiphlogistic remedies may also be used.

Mercury, however, yields to no other medicament in its powerful effect in subduing this disease: calomel should be given freely in doses of one, two, or three grains, every hour or two, until the mouth be affected, the breath fœtid, or the patient relieved; I say until the patient be relieved, because you will sometimes see in practice, that the disease will be subdued before the gums are rendered tender; and under such circumstances it is unnecessary to continue the remedy: if it should happen that the bowels are irritated by the calomel, then the hyd. c. cretâ may be substituted, or, what is far better, the free infusion of the unguentum hydrargyri.

Various derivatives have also been employed with the view of subduing inflammation, as blisters, sinapisms, rubefacients of different kinds. All these act probably in the same way, by producing counter-irritation, although Laennec imagined that a cataplasm, sprinkled with muriatic acid, and applied to the throat, would tend specifically to separate the false membrane; that muriatic acid, applied to the surface of the false membrane in the fauces, will tend to destroy it, there can be no doubt, but that it will so act through the skin, is very problematical. Warm baths are very much used in this country, and often with advantage.

To effect the expulsion of the concretions, emetics have been given once or even twice a day for some time, and often with complete success: hydro sulphuret of potash was formerly much used, from its supposed solvent quality, but its action is so slow that it has fallen totally into disuse.

Topical remedies of course cannot be used when the disease exists in the larynx, trachea, or bronchi; but I can speak from experience, that they are of great utility when it attacks the fauces, and I think its further progress is stopped by their prompt use. Various means of this kind have been adopted,—as alum, or the famous remedy of Van Swieten, which consisted of three parts of honey and one of muriatic acid: you will find one of the best, to be a solution of lunar caustic, in the proportion of six or eight grains to an ounce of distilled water; this may be applied by means of a little mop, made of a small piece of sponge or linen, fixed to the ex-

tremity of a piece of wood: use it two or three times a day, and, if possible, touch all the parts of the false membrane in sight freely.

If the danger be extreme, bronchotomy may be resorted to, by way of acting up to the maxim, that "*Anceps remedium melius quam nullum*:" but you must not promise yourselves much success from that operation, for it is impossible to determine previously, whether the false membrane has not descended below the point at which you would puncture the trachea: if this has been the case, then you would only add to the danger and distress of the patient. Bretonneau performed it with success on a child of four years of age, the daughter of the Comte de Puysegur. Bronchotomy has been repeated in this country in croup, but with little success.

Ulcerous Inflammation of the Mucous Membrane.—I shall defer the consideration of ulcerous inflammation until I describe Tubercular Phthisis, as it is an affection intimately connected with that subject.

DILATATION OF THE BRONCHIAL TUBES.

We now pass on to the consideration of the dilatation of the bronchial tubes.

History.—This morbid condition of the bronchial tubes was not known until it was described by Laennec, although it occurs frequently. The reason it was not previously discovered is very evident. When we examine a lung, we rarely open the trachea, and trace its ramifications; but we generally cut the viscus across, and it is then impossible to distinguish whether a tube is dilated, or of the normal diameter. You should open the trachea, and follow its branches, and if after a branch passes on to a certain distance, its diameter becomes greater, you may then consider it morbidly dilated.

Morbid Anatomy.—Dilatation of the bronchial tubes takes place in a variety of forms: it co-exists invariably with chronic mucous catarrh. A bronchial tube, that in its natural state would scarcely admit a crow's quill, will increase in diameter to the size of the finger. A tube may continue to a certain extent of its natural size, it may then dilate, and afterwards re-assume its proper dimensions: this is a common form to meet with. There may be a succession of dilatations and contractions along the same tube; sometimes the dilatation terminates in an irregular cul de sac, in which a number of small bronchial tubes open; in other cases, the bronchial tubes lose their form, and present a cavity capable of receiving a cherry or almond stone. Often many contiguous branches are unequally dilated, particularly in the upper lobes of the lungs, and form, by their communications,

sinuses full of puriform mucus, giving the appearance of a multilocular tubercular excavation. The extent of this disease varies considerably; it may occur in a single tube, in many, or even in them all.

The parietes of these dilated tubes also vary: they may be hypertrophied or atrophied. In the first case, the mucous membrane is most commonly from a third to a quarter of a line in thickness, softer than natural, and of a violet red colour; the sub-mucous cellular tissue is white, very firm, and of a fibrous texture; the cartilaginous rings are occasionally seen to enter into the substance of the parietes. In the second case, the dilated bronchi are of extreme tenuity, so that no remains of their primitive organization are apparent; they are then a little firmer than the healthy mucous membrane, red, and of a smooth internal surface: their tenuity becomes so great that they may be compared to the pellicle of an onion. The whole of the bronchial tubes of a lung have never been seen dilated in this manner, and the largest Laennec saw, would not have contained more than a nut, and it consisted of a number of bronchial tubes irregularly dilated, juxta posed, and communicating with each other.

These dilatations almost always occur in the upper lobes of the lungs, and towards their anterior edge: ordinarily a few branches are only affected, but sometimes all those of one lobe; then the dilatations are greater in the small ramifications than in the branches from which they arise, and greater in the branches than in the trunks from which they originate. The pulmonary structure which exists between these dilatations is almost always condensed, and no longer permeable to the air.

Causes.—Dilatation of the bronchial tubes rarely occurs, except in individuals attacked by chronic mucous catarrhs. It depends, doubtless, upon the prolonged stay of sputa in the bronchi, by which these vessels become gradually dilated. The bronchial ramifications, which enter into a tubercular excavation, are also occasionally dilated, and remain so even when these excavations are converted into fistulæ, the tubes generally preserving their cylindrical form.

Symptoms.—Local.—Laennec has given us the following description of the signs of this disease:—

When the bronchial tubes of the whole of a lung are dilated, the sound given by percussion is duller than in the natural state, because of the compression of the pulmonary tissue; but this sign is usually less sensible, except other circumstances contribute to produce the same effect.

In the points where the dilatations are greatest, pectoriloquy may be heard more

or less distinctly; it is accompanied by a mucous rattle, perfectly similar to the cavernous rhonchus of phthisical patients. Bronchial respiration is distinguishable on the same points, which an inexperienced observer would easily confound with the puerile respiration, because of its intensity. This sound becomes cavernous on the points of the chest, corresponding to the largest dilatations. The cough and mucous rattle have also the bronchial and cavernous characters in those dilatations which are nearest the surface of the lungs. The voice, respiration, and cough, often also give the sensation of the “*Souffle voilé*,” that is to say, of a thin veil, or humid membrane, floating and preventing the column of air from penetrating into the ear at each vibration.

Sometimes all these phenomena disappear for a certain time, particularly at the lowest parts of the lungs, because of the accumulation of mucous sputa: they reappear only after a copious expectoration, or a change of position.

When the dilatations are slight, and nearly equal in a certain number of tubes, there will be diffused bronchophony instead of pectoriloquy. When the dilatations are extensive, there will be found on all the corresponding parts of the thoracic parietes, bronchophony and bronchial respiration, and on some points only, perfect pectoriloquy.

Functional and General Signs.—Even where the dilatations are most extensive, the symptoms of the disease rarely indicate its gravity: most commonly there is no fever, nor marasmus. If the patient has no laborious occupation, he rarely feels a diminution of power: dyspnoea only occurs on rapid movement.

The expectoration is not characteristic; its abundance is only remarkable in very extensive dilatations: it is always mucous, or puriform, usually inodorous, occasionally of the smell of pus, or even of a fetid wound. Sometimes the sputa augment with such rapidity, that you might suppose a romica had ruptured.

It may be observed that the local signs of dilatation of the bronchi are common to several other diseases, particularly tubercular phthisis, abscess from peripneumonic inflammation, and gangrenous excavations: but the accumulation of all the signs can leave no doubt in the mind of the practitioner. We shall, however, enter into greater details of the diagnosis, when we arrive at the description of those organic lesions of the pulmonary structure, which dilatations of the bronchi simulate.

Treatment.—As the disease is a consequence of, or is complicated with, chronic mucous catarrh, it is evident that the only means of contracting the dilated tubes, is

by diminishing the secretion from the mucous surfaces. The treatment, therefore, is precisely the same as that recommended for chronic mucous catarrh.

BRONCHIAL HÆMORRHAGE.

By bronchial hæmorrhage is meant an excretion of blood from the surface of the mucous membrane lining the trachea and bronchial tubes.

Morbid Anatomy.—There is generally found a certain quantity of coagulated blood in the bronchial tubes, putting on the appearance of small polypi, which are merely the fibrous portion of the blood, often deprived of its colouring matter. The membrane itself is redder and softer than in the healthy state.

Causes.—This affection often occurs in young plethoric persons. It may be induced by circumstances which throw the lungs into considerable action, such as blowing wind instruments, hard exercise, and violent coughing. It will occasionally supervene upon the suppression of hæmorrhoids and the catamenia. The most common cause, however, is tubercular disease, and I confess that I look with more apprehension upon a small discharge of blood from the trachea than a large one, because the result is generally more dangerous. We sometimes find in epilepsy that a small quantity of blood is mixed with frothy saliva: its source is most probably also the bronchial membrane.

Symptoms.—The hæmorrhage is usually slight, spumous at first, but towards the end of the attack, the blood is coagulated. When the quantity is great, it is commonly caused by that state of the lung, denominated by Laennec, *Apoplexia Pulmonum*.

It is highly important to determine, whether the blood flows from the mucous surface of the bronchial tubes, or from the parenchymatous substance of the lungs. The absence of all the signs of the latter disease principally determines the diagnosis: thus, in bronchial hæmorrhage, there is no absence of respiratory murmur, nor is there crepitation on any point of the chest. When the hæmorrhage is slight, there is scarcely any acceleration of the pulse, nor does it present the hæmorrhagic vibration. Dyspnoea, heat and oppression beneath the sternum, scarcely ever occur in bronchial hæmorrhage.

Treatment.—General bleeding should be employed, if the patient be plethoric: opening a vein in the foot, or the application of leeches to the inside of the thighs, is a common continental practice, if the hæmorrhage appears to depend upon a suppression of the catamenia.

Various astringents have been used—as acids, alum, superacetate of lead,iced drinks,

cold air in currents: the most absolute repose and silence should be enjoined, and the absence from all stimulating liquids.

BRONCHIAL POLYPI.

Polypi of the mucous membrane of the bronchi are very rare: their structure is usually vesicular; that is to say, formed of a tissue analogous to mucous membrane, and inclosing small serous cysts. Laennec once found a concretion of an inch and a half in length, and four or five lines in breadth, attached to the commencement of the left bronchial tube, and nearly obliterating it. Its tissue was compact, and similar to the polypiform concretions found in the heart and arteries, but organization had evidently commenced, for it was firmer and less humid than these formations: its internal colour was white, mixed with shades of yellow and red; a few small blood-vessels were seen ramifying within it. On the external surface a still greater number of vessels were observed, and the colour was there of a reddish violet, particularly at its largest extremity. Laennec believes these concretions to be the fibrinous parts of the blood gradually becoming organized. We shall examine this opinion when speaking of the diseases of the heart.

CLINICAL LECTURE

ON

STRICTURE, WITH LACERATED URETHRA AND DISTENDED BLADDER.

Delivered at the Middlesex Hospital, November 1, 1834,

BY SIR CHARLES BELL.

Our subject to-day is Stricture, with Lacerated Urethra and Distended Bladder.

I have before me the house-surgeon's case-book, from which I am about to read. He promises me an abundance of cases of stricture, and disease of the urethra and bladder, if I will only defer the subject; but I shall be satisfied to-day with one case, which brings, I think, the whole question of practice before you, and in a very impressive manner. Before I read this case, let me beg you to consider two conditions of the bladder, apparently very distinct, and in contrast with each other, yet both proceeding from the same cause—stricture in the urethra. What, apparently, can be more distinct than a distended bladder arising above the navel, or even as far as to the scrobiculus cordis,

and a bladder so contracted, that its cavity is not larger than that of a walnut, and its walls so firm and condensed, that in old surgical books it is called scirrhus of the bladder, which scirrhus I hope you understand to be, the density arising from frequent and powerful muscular contraction? These two conditions, arising from the same cause, do yet present very distinct symptoms. Is the practice, then, different? Let us inquire.

With regard to the first, viz. distention of the bladder, you have before you a case which exhibits the extraordinary torture which the patient endures from it; and you must be anxious to know what would be the result if the patient were left unassisted. There might be rupture of the bladder; and observe, the bladder may be ruptured in two ways:—If a person with a full bladder is thrown from the top of a coach, of which we have had several instances in patients brought into this hospital, the coats may be actually ruptured, and the bladder rent from the fundus to the neck; but when rupture takes place purely from over-distention, which is the case now to be considered, the appearances on dissection are these:—There is a small pin-hole, or perhaps two or three small holes, with black and ragged edges, near the fundus, and the bladder itself is found relaxed and empty, whilst the abdomen is full of urine. It is not then, properly, a rupture, but something more like that ulceration which takes place in the urethra, and lays the ground-work of fistula. It is owing to the excessive distention that ulceration takes place, so as to weaken the coats, and then the urine bursts through them. When this happens, the patient feels as if he were passing water, yet no water flows. By and by, instead of the round firm tumor which was felt in the belly, there is a general tumor, and an undulation, implying that the urine is abroad in the cavity of the peritoneum. In the meantime the patient is probably delirious, and in that case a man will put a pistol to his head, or throw himself out of the window; such cases have been narrated to me. The only instance which I remember coming under my own observation, was one where the delirium arising from this source assumed so much the character of mania, that a physician from a madhouse was brought in to consultation. This was great ignorance, and to the effect of aggravating the suffering of friends; for is it not an additional pang to be led to believe that a son, or brother, has died maniacal? Such is sometimes the condition of a person with a distended bladder unrelieved.

When there is stricture, and a sudden

obstruction comes on, distention takes place; but when there is a stricture without such sudden and abrupt obstruction to the urine, the bladder makes powerful and frequent efforts to relieve itself; and these continuing, cause a thickening of its coats, and a diminution of its cavity, and from which, of course, arises a necessity for still more frequent calls. The patient is obliged to rise sixteen or twenty times in a night; he is at last continually on his knees, with the *pot de chambre* between his legs; he makes, perhaps, half an ounce of urine at a time, and that with such continued effort, and such protracted pain, that fever and irritation arise, and he will die with effusion on his brain. Mark, then, I beg, because it leads to an important conclusion in practice, how a narrowing of the urethra will at one time produce a sudden distention, such as we have just seen, and at another a condition of equal danger, but more insidious, in which the state of the patient is not so apparent, and yet the danger is imminent. You will readily acknowledge, that from either of these conditions a patient must be immediately relieved; that there is no time nor opportunity for gentler means; it is only an operation that can save him. I will now read the case of distended bladder.

Stricture, with Lacerated Urethra, and the Operation.

“A man of colour, of the name of Wallis, came to the hospital about half-past twelve, groaning most piteously, with retention of urine. Blood was flowing from the urethra, and it appeared that a surgeon had been called, who had attempted to pass a catheter for him, but had failed; and that the attempt to relieve him by operation had been followed by a great flow of blood. The surgeon then administered a dose of castor oil and laudanum; but the attempts by manual operation failing, he bled him and sent him to the hospital. When he came to the hospital, a wax bougie was passed down to the stricture and withdrawn, but no urine flowed;”—that is a practice on which I shall make some remarks presently;—“he was therefore immediately placed in the warm bath, but still no urine flowed. The finest silver catheter was attempted to be introduced; the point entered a very narrow stricture, but it could not be carried forwards; and below, a little to the left of the stricture, an extensive tear was felt in the membrane of the urethra. It was only by avoiding this, and keeping the point of the catheter close to the upper part of the urethra, that the point of the catheter could be directed into the stricture. No urine came, and the bladder being now

very much distended, and the fundus having risen to the navel, it was as tense as a tennis-ball." Such was his condition; and the narrative goes on to state—"that it was about twenty years ago that this man first suffered from an obstruction of urine; that he was then on a voyage to China, and, if we understood him aright, the water was drawn off by the use of a bougie. For several months past he has suffered much from stricture; he was obliged to rise frequently in the night, and on making water, it flowed in a very small stream. When he had desire to make water, if he did not immediately attend to the call, it would come away only in drops; however, up to this time he had always been able to do without an instrument, till the morning in which he was brought to the hospital.

"The case was becoming very serious, and the surgeon of the week was asked to see him whilst in the warm bath. He ordered him to be put between blankets, and carried to bed; and he then attempted to procure an impression with a soft bougie of the state of the stricture. He then introduced the catheter, but said he felt the point of the instrument out of the canal. A consultation was then held, and the attempt was made to pass two or three catheters of different sizes and curves, but in vain. On examining per anum, (the house-surgeon continues to state) the lobes of the prostate were felt distinctly, the gland healthy, the bladder tense in front. In the consultation, the question was mooted, whether the bladder should be punctured by the rectum, or the membranous part of the urethra opened from the perineum. The only objection to the latter method was the possible difficulty of introducing the catheter from the wound into the bladder, and the possibility, therefore, of the sphincter of the bladder still resisting, and the bladder remaining distended. It was determined that the latter operation should be performed; but if there were great difficulty of passing the catheter, that the bladder should be punctured in the wound, as it was declared necessary to relieve the patient immediately."

Now the house-surgeon has properly put down "*instruments prepared for the operation*—lithotomy-tapes, elastic catheter, grooved sounds, directorics, probes, sharp-pointed bistoury, tenaculum, bandage around the waist, trocar." In preparing to perform an operation, you ought to have every thing that can by any possibility be required. It is an unpleasant occurrence to be foiled in the first attempt, and then have to call for instruments which are not forthcoming, and which shew that something has occurred un-

expectedly, and for which no preparation has been made.

"The patient was taken into the theatre, and placed on the table in the posture for lithotomy, and secured in the usual way. The finger of the left hand was introduced into the anus, and the point of a sharp-pointed bistoury was thrust through the skin, about half an inch in front of the anus, exactly in the central line. It was carried at once into the membranous portion; the handle being then depressed, the point was pushed on, so as to come out through the skin, about an inch and a half in front of the part where it entered. By this the corpus spongiosum of the bulb must have been cut. The moment the bistoury cut itself out, a gush of urine followed, which covered the operator. The moaning of the patient immediately ceased; he seemed already relieved. After a time the catheter was put into the wound, and slipped at once, with the greatest ease, into the bladder. The whole operation together did not occupy half a minute. The urine continued flowing in a full stream, and about two quarts were evacuated through the tube. There was some arterial bleeding; but the loss of a little blood was considered as an advantage. The catheter was secured in the bladder, and the patient sent to bed. The surgeon, clapping him on the shoulder, said, 'Now, my man, you shall go to bed, and have an opiate, and be comfortable;' on which he thrust his head out of the blanket, saying, 'Sir, I am in heaven,' and drew it in again like a tortoise. His relief was so perfect, that he presently *fell asleep on the table*." Was this really so, gentlemen? I was obliged to leave him, and knew not the circumstance; however, nothing can so fully demonstrate his previous suffering and exhaustion, and the complete relief. For my own part, I have never seen this, except where I have operated on the trachea.

"When he became warm in bed, the bleeding increased considerably; and in a quarter of an hour he bled to sixteen ounces: it was arterial, and came by jets; but after the house-surgeon had searched some time, no vessel was found. It could only be commanded by placing the finger on the cut through the bulb. A small ball of lint, with a string attached to it, was placed there, another larger one over it, then a piece of sponge, and two large compresses, with a bandage over the whole; and this completely commanded the bleeding, without obstructing the catheter. The wire was passed to ensure that the catheter was quite clear. The pulse strong, and full enough. He had lost about twenty ounces of blood.

"Eleven p.m.—No more bleeding; the

stilette again passed; all but the two lower compresses removed, for fear of too much obstruction to the urine, and that the catheter should get choked in the night, and so inject all the cellular membrane.

"31st.—Passed a good night; pulse full, rather variable; no pain in the abdomen; urine trickles freely from the instrument as it is secreted. Poultice to the wound."

REMARKS.—1. Now you have heard the case, and you will not accuse me of a want of decision, nor an unwillingness to operate when the occasion calls on any idea of the difficulty to be encountered; and therefore I take this opportunity of strongly impressing upon your mind, that if I seem unwilling at any time to operate, it is from another reason, than any distrust of my hand. And further, I take the opportunity to assure you, that though you have seen me, with a knife, cut at once into the perineum, yet in general practice, gentleness, perseverance, repeated slighter efforts, are the sure modes of curing stricture in the urethra; and not one case in five hundred requires any such means of relief. True it is the time may come when you require decision and a bold operation, such as you have seen me forced to perform; and as it may become necessary, you ought to prepare yourselves for its performance. But if time be afforded for gentle means, they are much to be preferred, and are surer to be successful;—I mean in cases where the stricture has not been abused.

2. The next question that arises is, What is the nature of this obstruction? Is it altogether mechanical, or is it partly mechanical and partly nervous or spasmodic? You must remember, that if a person have his bladder surcharged, though there be no obstruction at all, it will cease to act. I have this morning drawn off two quarts of water from a gentleman's bladder, where there was no difficulty whatever in passing the largest catheter, for I used the largest catheter purposely; but the bladder had been over distended, and consequent upon that there was paralysis—or at least, if not paralysis, a want of consent between the detrusor of the bladder and the muscles in the perineum. You no doubt remember that the neck of the bladder and the urethra have around them the compressor prostatae, levator urethrae, and the ejaculator seminis, besides the columns of the levator ani. All these muscles must relax before a drop of urine comes, and any spasmodic action in them directly obstructs the passage, whilst it hinders the contraction of the bladder itself. The contraction of the one set of fibres, and the relaxation of the other, belong to the same

act, like the condition of opposing muscles in the motions of the limbs; so that if the bladder be not in a state to execute its functions, these muscles are not in a condition to relax. It would be easy to illustrate this by the state of the stomach, the rectum, the uterus, or any hollow viscus. When a man has a stricture, and passes his urine with difficulty, being in the condition that this case describes—that is to say, unless he immediately attends to the call to make water—he will soon be unable to void it at all: he is liable to have his bladder surcharged; and no sooner does it become distended, than the fibres at the cervix become spasmodic. Then the bladder fills more and more, till it rises, and may be felt in the abdomen, and so it may to the umbilicus, or even to the scrobiculus cordis. You perceive, then, that although the original cause—the stricture—be a mechanical obstruction, there is superadded a cause *spasmodic*; and it is the management of this spasm that demands your attention—not the immediate cure of the *stricture*. This is the reason why the soft bougie was used, as the man describes in his case, and why it was again attempted when he was brought into the house. By passing the wax bougie, with the end softened, into the stricture, letting it remain there, and slowly withdrawing it, calling upon the patient at the same time to make an effort, and gently pressing the abdomen, the urine will sometimes flow; and when it once begins to do so, it continues. You understand, also, that it is for the same reason that the patient is bled, and put into the bath, and has a strong opiate administered.

3. It is a common question with us, when examining whether a pupil or a dresser be fit to be made house-surgeon, to ask what he would do when a man comes in with obstruction of urine? You see how necessary it is that he should be perfectly aware of what ought to be done, because such cases are occurring almost every day; and if he makes a mistake, and passes a catheter at an improper time, the case before us declares with sufficient emphasis what are the unhappy consequences. It is expected he should reply, "I would consider from what the obstruction proceeded. If he were an old man of seventy that presented himself, I should suspect the prostate, and examine that first, to see if it were enlarged. If he were a young man, I should ask him if he had been the subject of gonorrhœa, of discharge from the urethra, and if the discharge had been suddenly suppressed," because when the inflammation of gonorrhœa is suddenly checked, it is, in fact, travelling backwards; the discharge has not merely ceased, but the inflammation of

the urethra has increased, and very often it is the violence of the inflammation which stops the secretion. There is a certain degree of inflammation which promotes discharge, but a little less or a little more suspends it; and when gonorrhœal inflammation has increased to a considerable degree and crept back to the neck of the bladder, pain and spasm take place of the discharge. We should therefore require the house-surgeon to consider whether the obstruction arise from inflammation, and consequently spasm and impediment to the action of the bladder, or to stricture. I should expect him to say, "I must consider whether the patient has not got a stricture, for although I might draw off the water from an old man with an enlarged prostate, yet I am aware of the danger of attempting the same mode of relief where there is a narrow and irritable stricture;" and I should expect him to add, "whichever of these three causes the distress arose from, I would be careful in passing the catheter." As surgeon to a public institution, I should especially require attention to ascertain the nature of the obstruction, with reference to these three questions, before I would say he was a safe man.

(3.) In such a case, then, as I have read, where the history tells us there is a stricture, and the surgeon who first attempted to overcome it has ruptured the urethra by allowing the point of the instrument to get out of the right canal, we are precluded from doing those delicate operations which require repetition, and therefore time, to be effectual. When the point of the catheter has lacerated the membrane of the urethra anterior to the stricture, there will the bougie hitch and fall on every repetition; so that you are not only prevented from gradual dilatation, but even from that milder mode—gentle insinuation of the bougie, in order to induce relaxation of the spasm. Now comes the question home to us: where the bladder is rising, the torture extreme, and delirium is coming on, what is to be done? Is the bladder to be punctured, or are you to perform an operation on the perineum? I would say, the bladder is not to be punctured unless in some extreme cases, where the patient is so far gone from distention and inflammation, accompanied with long continued agony, that a little further delay will destroy him; and where he is not only gone very far indeed, or where there is a great complication of disease about the neck of the bladder. If a patient in this condition be put upon the table, and you commence an uncertain operation upon him, keeping him half an hour or an hour under repeated incisions, and poking with probes, and ineffectual endeavours to pass the elastic gum

catheter into the bladder, he begins to vomit; the stomach sympathizes with the general suffering, and when he is put to bed he never recovers: he falls into a doze, or delirium, and you have destroyed him by a little too much excitement or irritation; you have thought by your dexterity to relieve, but you have failed in your expectation in that—you have erred in judgment, and your patient is lost. In such a case it may be necessary to pass the instrument into the rectum, and from thence into the bladder, and without pain, without irritation, without delay, to relieve him. But these are rare cases, and it is better to cut in the perineum, because you not only relieve him, but lay the foundation for a perfect cure. Still, however, much will depend on his condition.

I remember when it was a regular question (I need not say where), How long are you to wait before puncturing the bladder? You perceive the degree of distention is no criterion, because, after the bladder is distended to a certain degree, the urine drips away continually; and therefore a man may have a distended bladder to-day and may not be worse to-morrow, in consequence of the bladder permitting the surcharge to drip away. I need not remind you that an ill-educated surgeon is apt to be mistaken here just as the patient is. A patient calls you to his aid for incontinence of urine, but, upon examining the case, you soon find that he labours under retention; that the water which is dripping from him leaves constantly a couple of quarts perhaps in the bladder, which is the source of painful distention and inflammation. My object in stating this, is to shew you that it is the degree of suffering which, after all, must determine us. A bladder which, in consequence of stricture, has become so permanently contracted that it has not for many months contained more than two ounces of urine, must give excessive distress, and cause inflammation if distended; when a natural bladder will suffer greater distention without so immediately producing inflammation.

The degree of suffering, the roundness, firmness of the distended bladder, and tenderness of the abdomen, are our best indications. I would say, that when once you feel the bladder above the pubes, like a round ball under your hand, as tense as it is described in this case—the pulse excited, and the man's mind excited in an extraordinary degree—you must adopt the same rule as in hernia; *not to leave the house till he is relieved.*

(1.) Now comes a question of extreme delicacy, as it is to be expressed before you, and touching an operation of extreme delicacy; I mean forcing the stricture with a catheter. I acknowledge that

I have a narrow-pointed catheter; not sharp, but small, round, and smooth; with which I have sometimes saved the necessity of a more formidable operation, by passing it through the stricture. But it is to be done with fear and trembling; because, although you may succeed in putting the man (as this patient said) "in heaven,"—and I have heard the expression before—yet, on the other hand, you may rupture the urethra. In performing the operation, you must place the patient fairly before you, take care that the instrument is exactly in the centre, introduce it down to the stricture, put your finger in the perineum, and try to get the point of the instrument into the stricture. If you can feel it in the stricture, and, on attempting to withdraw it, find it is held, you may be certain that it has not passed in a false direction; and then, by slowly going on, and gently driving the instrument forward through the stricture, at the same time drawing the integuments of the perineum forward, and then introducing the finger in ano, and so carefully watching the progress of the point until it gets into the enlarged part of the urethra, you may thus save the patient. But I need not remind you of the danger of the operation; the case I have read sufficiently shews it.

(5.) With regard to puncturing the bladder, it may be done above the pubes, by the rectum, or by the perineum. But I have already stated that it is only in extreme cases, when there is much disease, and the person is just, as it were, upon the brink of running into a state of inflammation and fever, and delirium, that you can think of puncturing the bladder: the more legitimate operation is that which you have seen performed, or heard described.

When we speak of an operation in the perineum, the first thing to be thought of is cutting the stricture. This is an operation of great delicacy: see how it is done. The patient is placed on the table, as for lithotomy; the incision is made in the perineum, and a grooved staff is passed down to the stricture, and the point cut upon, by which you get it into the urethra anterior to the stricture. You then pass a fine probe from the anterior part of the stricture, through the stricture; and if you succeed in this the operation is easy, for then you have just to feel the probe with the knife, and cut along it. When a patient has suffered what I have described, that part of the canal behind the stricture is enormously enlarged, and we have no difficulty there; the difficulty is in striking the stricture, and if you cannot get a probe through it, you must divide the callous part without a director, the object being to get into the enlarged part of the canal; you then pass a catheter through the penis, across

the stricture, into the posterior part of the canal, and from thence into the bladder. The wound is then to be healed over the catheter. This is a pretty operation, when adroitly performed. But I say again (and I think many here have seen the operation attempted both in my hands and those of others), that it may be a tedious and uncertain operation, and is therefore not to be inconsiderately undertaken: you must be certain that the patient can bear the continued fingering, teasing, and cutting.

I have, then, to direct you to what you have seen here: the operation was done by cutting into the urethra posterior to the stricture. I have performed it (and I believe other surgeons have done the same) in a different way to what you have now seen—viz. by a cut of the scalpel upon the face of the perineum. Why have we changed the mode? I will tell you why, and it is important that you should know it. If you have a small gland to cut out about the breast or axilla, you feel it very distinctly through the skin before you begin; but when you have made your cut upon it, and when you have got your fingers among the fatty membrane, you cannot find it—it seems to have disappeared, and you dissect at random. It is very important to remember that you can distinguish such a body outwardly, before the incision is made, much more easily than when you have cut through the skin and are closer to it. So it is in respect to the parts in the perineum: it is possible, by introducing the finger into the anus, to distinguish the prostate, its two lateral lobes, its centre, where the membranous part of the urethra enters it; and this in a manner much more distinctly than when a cut is made through the integuments and the finger is in the wound of the perineum. Recollecting the difficulty of hitting the urethra after a deep incision, or of feeling the prostate among dissected parts, I thought it would be better if I put my finger in the rectum, to see that I was exactly in the centre, where the urethra traverses the prostate; and I then passed the sharp-pointed bistoury, directed by the finger (although the walls of the rectum were between the instrument and the finger). Besides you have here, in this mode of operating, a great advantage in the steadiness of the patient. When you pass a narrow bistoury through the skin, it is not more painful to him than the puncture of a needle; and when it is introduced, you can direct the point of it with great nicety. And now observe, when you think the point of the instrument has struck the membranous part of the urethra, depress the hand, and bring it out: by this the bulb of the urethra is cut, as it is very properly stated in the case.

You will please to observe, that the incision of the bulb being in the very central line, we do not touch the larger branch of the artery, as we do in cutting for the stone. Were it at all an object, I could introduce the point of the knife forwards in the perineum and round the prominence of the bulb; but I do not think there is sufficient reason for this, seeing that it is my principal object to have a free wound; that is, penetrating to the urethra, but large outwardly.

It has been stated that the patient ought, in this circumstance, to lose blood; and he cannot lose it from any part with greater advantage than from the bulb. This mode of operating relieves, whilst it is laying the foundation for a permanent cure.

I shall conclude by giving some advice to the house-surgeon. How is he to perfect the cure in this case? He is to begin to work upon the stricture; and let me remind him, that he is not to destroy the natural membrane of the urethra if possible. If you remove a stricture by caustic, or cutting, or by destroying the natural membrane, and substituting another, the latter never answers the purpose perfectly, or at least permanently. The natural membrane of the urethra is elastic in the finest degree, yields to the push of the urine; but if you have formed a membrane out of the cellular texture by condensation and inflammation, it has always a disposition to contract, and you have got a patient for life—that is to say, the man must always come back to have his stricture dilated. It is cruel to the patient, and putting yourself in a questionable position with regard to the honour of the profession to act thus, and therefore avoid it. I repeat, then, that the house-surgeon must, by gentle means, try to dilate the stricture—try to cause absorption of the coagulable lymph outside the membrane; and when he can pass a considerable instrument into the bladder, he will withdraw the tube from the wound, introduce a catheter along the penis, past the incision, and into the bladder, and so heal the external wound over it.

But again, if he finds unusual difficulty in the introduction of his bougie into the stricture, he will have to reverse the introduction of it, and passing it from below, prosecute his cure in that direction. I should regret the necessity of perforating the stricture; but if it must be done, it will be performed with comparative ease, when an open tube is pushed up to the stricture from below, whilst the perforator is introduced from above. I believe you are pretty well convinced, from what is passing around you, that the complaint of stricture is common enough to deserve all your attention.

OBSERVATIONS ON DIABETES MELLITUS,

AND ON

CALCULUS PASSING FROM THE KIDNEY.

To the Editor of the Medical Gazette.

SIR,

In the year 1824 I published a case of diabetes mellitus in *M. Magendie's Journal of Physiology*. I was then residing in Paris, and the patient whom I treated was an inmate of the house.

Upon a perusal of the case, it will be evident that the bleeding, which must have been considered by the editor of the journal as entitled to the credit of the cure*, formed only a part of the treatment, and perhaps not the most important part. Suffice it to say, that the woman was completely cured, and that, after a period of ten years having elapsed, I am enabled to assert that she has had no return of her disease.

Seven years' residence in Russia has confirmed me in the opinion which I then formed, of the efficacy of the vapour bath in restoring the secretion of the skin; and I am disposed to believe that my patient was cured, not by the bleeding, but by the use of this bath, to the efficacy of which, however, venesection may have greatly contributed.

If my view of the case be correct, it may lead to a more general and early use of this agent in the treatment of this obstinate complaint. The patient is still residing in the same family as she was when I treated her in 1824; so that I have the means of ascertaining that she has suffered no relapse whatever since that time, a period of ten years. I shall transcribe from *M. Magendie's journal* (tome iv. an. 1824) the principal features of the case.

Louisa Subiron was about fifty years of age when she first consulted me. She was rather corpulent and healthy in appearance, but subject to nervous attacks, and rather disposed to melancholy.

She had been indisposed for some little time previous, and had concealed her complaint from motives of delicacy; but was compelled at length, from the ur-

* "Histoire d'une Diabète guerri par une saignée." This is the title prefixed to the case by the editor of the journal.

gency of the symptoms, to reveal it. She was tormented by continual thirst, which she could not assuage by any quantity of fluid which she swallowed, although she drank from twelve to fifteen pints daily. She slept ill, and her tongue became very dry during the night; the skin also was dry and rough, and she could not excite perspiration by any of the ordinary means employed for that purpose. The bowels were constipated, and the digestive and nervous systems were much deranged. She made no mention at this period of the abundant secretion of urine; she considered the thirst as the chief disorder, and feared that she should become dropsical, as several of her family had died of that disease.

As soon as I was aware of the nature of her case, I took the first opportunity of sending some of the urine to M. Chevreul for analysis. He found that it contained a very large proportion of sugar. At this time the patient voided about fifteen pints daily.

I decided upon bleeding her, because she had, previous to this affection, suffered much from pain in her loins. Twelve ounces of blood were taken away. The blood formed a loose coagulum. She felt very much relieved for the time being, and all the symptoms diminished except the dryness of the skin.

I insisted upon her eating animal food only with a small proportion of bread. She drank equal parts of milk and lime water for common drink, and took ten grains of Dover's powder at bed-time. She used the warm bath every evening. Constipation was relieved by small doses of calomel and colocynth.

Soon after the bleeding the urine was reduced to eight pints daily; but it again increased, and a second bleeding to the same extent was resorted to. The blood was firmer in consistence than on the previous bleeding. The patient again felt much relieved, and said she was stronger than before she was bled. Two days after the second bleeding the urine diminished a third, and it had a decidedly ammoniacal smell. It still, however, contained a portion of saccharine matter.

As none of the means hitherto employed had succeeded in exciting perspiration, and as I trusted to the re-establishment of this function as the

chief means of cure, so I determined to try the effects of the vapour bath.

The patient was exposed to a temperature of 45° Reaum. She perspired most profusely, and changed her linen three times during the evening. She found herself better the following day, but weak. She walked, however, the distance of a mile, warmly clad, and perspired freely. The urine was reduced to five pints daily. She repeated the bath five days afterwards, but could not support it so long as on the former occasion. She perspired most profusely immediately after the bath, and continued to do so moderately for several days afterwards, without using any means to promote perspiration. From this period all the symptoms of the disease vanished; and the urine, which was analysed four months afterwards, contained no particle of sugar.

Paris, November 1824.

Such was the treatment, and its results. at the time I published this case in M. Magendie's Physiological Journal.

I was then residing in Paris, and unacquainted with the use of the vapour bath, except as a medical agent. It is only after some years' residence in St. Petersburg that I am acquainted with it, as a means used continually by all classes of people for purposes of personal cleanliness.

The vapour bath is a *sine qua non* of a Russian boor's existence. The soldiers and sailors use it twice, and the peasants at least once, a week. Baths abound in the capital; and in every village where there are twenty houses, there is one devoted to the purposes of a bath. People of all ages use them, and the heat, generated in various ways, soon throws the person into a profuse perspiration. Sometimes dry heat is employed, and the individual stands in the bath as in an oven. Vapour is produced by dashing cold water upon hot stones. The bather generally lies upon a plank in the hottest part of the bath, and is flagellated with soft rods, or he is scraped down with a kind of hoop, or rubbed with shavings or hair brushes.

Whichever of these processes he may undergo, and he has his choice, as also of his grooms, the effect produced is a profuse perspiration from every pore. When this has continued a certain time, warm water is dashed all over him, and then water a little cooler, and finally

water at a very low temperature. This is succeeded by dry rubbing, which produces a genial glow; and as the operation is generally performed of an evening, he retires from the bath to the bed or couch, and perspires moderately for the remainder of the day.

Such are the means employed by the people for the purposes of personal cleanliness; but the baths are employed medicinally, with frequent good effect. It is evident that no stricture can exist in the capillary vessels, nor that the function of these vessels can be altogether performed vicariously, when such excitement is produced as these baths necessarily procure.

As these circumstances are of daily occurrence, knowing the effects of the bath, and seeing its general use, I was induced to examine whether diabetes was a rare disease in this metropolis. The food of the people, which is much more saccharine than that of most other nations (the bread being made of rye, and sweeter than wheat bread), and the long fasts obliging them to live for months in the year upon bread and vegetables, would *à priori* militate in favour of the frequency of this disease.

It seemed probable, however, that the general and frequent use of these baths, by determining so much to the surface, would prevent the kidneys from usurping to such an extent as they generally do in this obstinate complaint, this function of the skin. Upon inquiring as to the frequency of diabetes, I found that it was a disease hardly known in Russia. Sir James Wylie informed me, that he had never seen a case among upwards of two millions of soldiers, whom he has in his long and useful career inspected. Dr. Trevennins, a physician of great eminence, and formerly in very extensive practice both in Petersburg and in the interior, has never met with a case. I can find no instance of this disease recorded in the list of maladies entered in the books of the civil or military hospitals for the last twenty years. I might mention also the names of many private physicians, who have never had an opportunity of witnessing diabetes in their Russian practice.

Such evidence may perhaps be considered more than of a negative nature in ascribing the prevention of this disease to the employment of baths, which excite general perspiration. It is not

probable, that as long as I remain in Russia I shall have any positive evidence in their favour as regards the cure of diabetes; but I feel confident, by the success which I experienced from their use in the case which I have related, that much good may be expected from them when employed early in the disease.

I am aware that they have been before recommended in the treatment of this complaint, and that many have relied solely upon exciting cutaneous perspiration for the cure. For this purpose patients have been made to walk in the sun covered with blankets, as a sudorific means. It is therefore only in corroboration of the benefit to be derived from this plan of practice that I have ventured to offer these observations, which amount to negative evidence at least in its favour.

I know not what changes may have been operated in the habits of the English with respect to baths in general, but a residence on any part of the continent convinces us that baths are less employed in England than in any other country; which seems an anomaly in the habits of a people who are celebrated abroad for their *propreté personnelle*.

Case of Calculus passing from Kidney.

In the autumn of 1833, about the month of August, I was informed by a gentleman, who consulted me, that his urine was as highly coloured as porter; and although he felt no inconvenience in any respect, as regarded his general health, he thought it was well to mention the circumstance to me. I recommended him to drink soda-water, and he did so for some days.

A month or six weeks after this occurred, he caught cold from hunting in wet weather, having been exposed for several hours to rain and wind, and getting wet in the flanks; and on the evening of the same day was attacked with what he supposed to be a fit of the colic, and he took some rhubarb and port wine, which were given him by some of his friends in the country.

As the uneasiness continued for some days successively, he again applied to me, and I gave him a good dose of castor oil, which produced its effect. One morning early, and a few days after this supposed colicky attack, I was summoned to him, and found him suffer-

ing very severely from pain in the right side, under the ribs, in the region of the right kidney, and extending towards the navel.

The pain seemed of a spasmodic nature; it was not increased by pressure; there was no one particular spot which was more sensible to the touch than another; the whole seat of the uneasiness occupied a space which might be covered with the palm of the hand. The pulse was not in the least affected; no headache nor fever; there was some vomiting, but no sensation in the testicle, nor any numbness of the thigh, nor any pain in the direct line of the ureter. There was no eructation nor flatulency, nor did the evacuations produced by clysters produce any sensible relief.

Fomentations, cataplasms, and opiates, relieved the symptoms; but for at least ten days afterwards there were repeated returns of the same uneasy feeling, which came on without any warning, and at no particular time or period, and left the patient afterwards totally free from pain, so that he pursued his occupations as usual, took the same hard exercise, and frequented society, although the pain would, from its sudden invasion, often oblige him to quit the drawing-room suddenly. The whole attack and its sequela lasted about three weeks. Small doses of calomel and opium, leeches applied to the part, warm baths, fomentations, clysters of linseed-tea with laudanum, castor oil, taken by the mouth, formed the whole of the treatment upon this first attack.

From the month of September till the month of December following, the patient had no return of these symptoms, and hunted and took his usual exercise, without any inconvenience; but in the middle of this month I was sent for to him, and found him labouring under very severe pain, which made him writhe his body from the torture. The attack began suddenly about 11 A.M., and as soon as it commenced he took a dose of castor oil, which he soon rejected from his stomach. He informed me that his water had been turbid for some days previous. The pain occupied the same spot as before, unaccompanied, however, by any nephritic symptoms. I gave him ten grains of calomel and one of opium in a pill, which relieved the pain in a few hours; but the vomiting continued, and

castor oil had been twice rejected from the stomach, the bowels remaining locked. I took about fourteen ounces of blood from the arm. The blood presented no unusual appearance, but the bowels yielded several times immediately after the bleeding. This attack passed off as the previous one, but uneasy feelings remained for some time in the loins. The patient was recommended to pay very strict attention to his diet, and to take a blue pill once or twice a week, with some Cheltenham salts the following day; but this plan was never put in execution. As it appeared to me probable that the kidney was the seat of the complaint, I directed him to observe his water regularly, that no sand or particle of stone might escape without our notice. The patient remained free from complaint till the night of the 5th February, 1834, when I was sent for to him, and found him labouring under a very severe attack of his complaint. The symptoms did not differ from those of his preceding attacks, except as regarded the vomiting, which was more constant than before, and it seemed for the time to relieve his pain. I examined his urine; it was of a light straw-colour. An injection of linseed tea, with two ounces of castor-oil and a drachm of laudanum, were administered. Soon after its administration the patient fell asleep, and when he awoke he was free from all pain, but vomited every thing which he took into his stomach. He had no headache or fever; the skin was cool, and occasionally moist, and the pulse quite natural. The vomiting was allayed by saline effervescing draughts, but the bowels were constipated, and the anodyne enema not having returned, another, composed of senna and Epsom salts and a drachm of aloes, was administered. This produced two motions only. Several purgatives were subsequently administered, and as the patient felt his digestion impaired, he consented to take some blue pill regularly. He continued the pills for two or three days, but as he imagined that his gums were affected he discontinued them.

He remained free from inconvenience till the 24th of May, when he had another slight attack, which yielded to the warm-bath and opium in a few hours; but it was subsequently followed by considerable pain in the loins, and he attributed the attack to leaving off sud-

denly a flannel belt, which he had been in the habit of wearing. During this last attack, which was shorter than any of the preceding, the nephritic character of the complaint was more marked. The pain was more immediately in the seat of the right kidney, and there was, for the first time, considerable retraction of the testicle. The patient found it difficult to retain his water, and complained of a sense of numbness in the glans penis and spasm of the urethra, in expelling the last drops of water.

He has had four of these attacks in the space of eight or nine months, and each has been apparently excited by violent athletic exertion and exposure to cold. A few days after the last attack, I was informed that he had passed a very uneasy night, from continual pain in the urethra, about an inch from the orifice, and from a constant desire to make water. His shirt was spotted with drops of blood, and he told me, that after each attempt to void his urine he observed a drop of blood at the orifice of the urethra. He moreover informed me, that in making water it suddenly stopped in its passage, and then came out in a forked stream. The chief uneasiness was felt in the urethra. Sometimes the pain was dull, but sometimes of a sharp spasmodic kind. All the uneasiness which he had previously experienced in the loins and in the region of the kidney, all the nephritic symptoms had ceased, and now all the inconvenience was felt in the bladder. It was evident that something had passed from the kidney into the bladder, and the patient was strongly urged to be sounded; but as he was about to take a journey, he refused to suffer this operation until he returned, which was about fourteen days afterwards. He suffered a good deal of inconvenience from the jolting of the carriage, and the pain in the urethra was increased. His water stopped suddenly in its passage, and he felt externally that there was some foreign body in the canal. The medical man who came to his assistance extracted a rough-shaped calculus, which was broken in the operation, and a considerable portion of it was lost. The extraction of it created great local pain, but this was not succeeded by any constitutional irritation, and the patient soon felt relieved from all his complaints. The portion of the calculus which he

gave me for analysis weighed six grains. It was analysed by a good chemist, and was found to be oxalate of lime pure.

It was ten months from the first uneasy symptoms which the patient experienced until the calculus passed into the bladder. True to the character of the mulberry calculus, there was never any deposit in the urine.

Your obedient servant,

GEO. WM. LEFEVRE, M.D.

Physician to the British Embassy, St. Petersburg.

St. Petersburg,
September 1834.

ON PHLEBOLITES, OR CALCULI IN THE VEINS,

AND CONVERSION OF THE COATS OF VEINS
INTO CALCAREOUS MATTER.

By ROBERT LEE, M.D. F.R.S.

PHLEBOLITES have been found most frequently in the veins which return the blood from the uterine organs, the bladder, prostate gland, and rectum; but they have been met with also in the veins of the spleen, spermatic cord of aged men, the anterior and posterior tibial veins, and in varicose subcutaneous veins of the leg. Otto found them most frequently in the veins of the uterus, vagina, and bladder of persons who were more than fifty years of age. He discovered them once within the veins of the prostate in an old man. In all the cases the veins were varicose, and contained coagulated blood. In two instances gouty concretions existed at the same time in the joints; and such was the case in the man in whom the calculi were found in the veins of the prostate. Otto refers to Realdus Columbus for an example of phlebolites in the hemorrhoidal veins, and to Bartholin, Tulpius, and Walter, for the history of cases where they were found in the renal, meseraic, dorsal and vesical veins. Mr. Langstaff saw three calculi as large as peas in the veins of the uterus, and he has observed them also in the veins of the prostate, and he thinks they are formed most frequently in those who have diseases of the prostate and bladder*. Lobstein has found them in the veins of the testicle, uterus, bladder, rectum, and once in the veins of the spleen†. Tiedemann found numerous

* Hodgson's Treatise, p. 522. 1815.

† Traité d'Anatomie Pathologique. Paris, 1829.

concretions in the varicose veins of both spermatic cords of a man fifty-one years old. There were fifteen of these calculi in the right; in that of the left twenty-one. They were of different sizes, of a round or oval form, had a yellowish white colour, and lay loosely imbedded in coagulated blood. Some were, however, adhering to the inner coat of the vessel by a fine transparent membrane.

In one case the writer discovered several phlebolites in the spermatic veins of a lady who died at the age of thirty-five, and who had suffered repeatedly from abortion, and once from inflammation of the uterus. In a case which we examined with Mr. Holberton, of Hampton Court, where the mucous membrane of the rectum was ulcerated, we found several phlebolites in the left hemorrhoidal and vaginal veins. One of these was as large as a pea, and smooth on the outer surface; there were two others much smaller, which were deposited in the centre of small clots of the fibrine of the blood. The fibrine surrounding these was formed into thin concentric layers. The coats of the veins surrounding these bodies were healthy, but between these points and the ulcerations in the rectum their coats were disorganized by inflammation. We have repeatedly met with phlebolites perfectly or imperfectly formed in the spermatic and hypogastric veins of women who had died from malignant disease of the uterus. While engaged in writing this article, 24th July, 1833, we found a phlebolite of an oval shape, smooth on the outer surface, and about two lines in diameter, in the anterior tibial vein of an aged woman, who died in the St. Mary-le-bone Infirmary of cancerous ulceration of the bones of the face. The coats of the veins enclosing the concretion were thin and pellucid: over the tibia, two inches nearer the ankle, there was the cicatrix of a large ulcer. An aged female, with varicose veins, now under our care, has a large phlebolite in the anterior tibial vein of the right leg, which produces little or no uneasiness. In the right common iliac vein of Lord Liverpool there was contained a cylindrical concretion, an inch or more in length. Sir Astley Cooper, to whom the writer is indebted for an opportunity of examining this rare specimen, believes the deposit of calcareous matter to have taken place within the vein, and consequently that it is not an example of ossification of the coats of the vessel, as had

originally been suspected. The iliac and femoral veins of Lord Liverpool, on the opposite side, had been completely disorganized by inflammation. It does not appear that phlebolites have yet been observed in the sinuses of the brain.

Phlebolites often attain the size of a common pea; more frequently they are smaller, and sometimes they do not exceed a millet-seed in size. Otto states that he saw one in the anatomical museum at Strasburgh of the size of a hazelnut. They are usually of a yellow colour, and consist of concentric lamellæ, and are more frequently of an oval than round shape. According to the analysis of John and Gmelin, they are principally composed of carbonate and phosphate of lime with animal matter. Dr. Prout has more recently analyzed some of these concretions, and his results are nearly the same.

A difference of opinion has prevailed respecting the mode of their formation. Mr. Hodgson thought it not improbable that phlebolites were formed in the surrounding parts, and made their way into the veins by progressive absorption. Meckel entertained an opinion that they were formed like encysted tumours. Andral states that calculous concretions sometimes push the internal membrane before them, and descend with them into the cavity of the vein. The membrane, he adds, becomes thin, and forms a true peduncle to the concretion. There is the closest analogy, M. Andral thinks, between these pedunculated concretions and those concretions sometimes met with in the interior of the joints, and he inquires whether it may not be possible for these bodies sometimes completely to detach themselves from the coats of the veins, and become loose in the cavity. Tiedemann believes them to be formed from the blood itself: this opinion Otto states is also supported by the observation of Errhman, according to which some of the concretions were still soft, and appeared to be formed from the fibrous matter of the blood—a mode of formation which Cruveilhier had previously noticed. That this view of the mode in which phlebolites are formed is correct does not admit of dispute, and Dr. Carswell has executed drawings to illustrate the various stages of their formation. The observations of Dr. Carswell prove that there is first formed a small coagulum of blood in the vein, and that in the centre of this clot a little nucleus with concentric lay-

ers gradually appears. By and by the red part of the blood is partly absorbed, and the fibrine makes its appearance with the usual physical characters. Then a certain arrangement can be perceived taking place in the fibrine forming lamellæ, the central one first formed apparently becoming cretaceous; and this cretaceous induration takes place throughout the different lamellæ until the whole is converted into a solid phlebolite. In the point towards the distal extremity of the vein there is sometimes a little nucleus of blood or fibrine, which becomes a concretion; and thus the phlebolites sometimes get a caudal extremity.

But in what manner the blood becomes coagulated in the veins so as to give origin to the formation of phlebolites, it is not so easy to determine. That this is sometimes the result of a slight degree of inflammation or irritation propagated from diseased organs along the vessels, is highly probable, from the facts already noticed respecting the consequences of phlebitis. It must, however, be admitted that at the part where the phlebolite is formed there is in general no perceptible alteration of structure in the surrounding coats of the vein, although it has been employed in bringing back the blood from a diseased organ.

The conversion of the tissues which compose the veins into calcareous matter takes place so seldom, that Bichat questioned the possibility of its occurrence. The lining membrane of veins, he observes, does not become ossified in aged persons, as we observe in the arteries; its organization prevents it from being penetrated by the phosphate of lime. When it does happen, it is an unnatural condition; whereas ossification of the common membrane of red blood is a state almost natural to the aged*. Morgagni has, however, related a case in which the coats of the vena cava were in great measure cartilaginous, and even in some degree bony†. Dr. Baillie mentions an instance where a considerable ossification was found in the coats of the vena cava inferior, near its bifurcation into the two iliaes‡. Dr. Macartney informed Mr. Hodgson that he met with several depositions of cal-

careous matter in the external saphena vein in a man who died of a diseased liver. There was an ulcer on the leg; but the depositions of calcareous matter appeared to have no immediate connexion with the ulcer. One of the depositions was nearly an inch in length, and was situated on the internal surface of the vessel*. Beclard found the femoral vein ossified at one point where it was in contact with the crural artery, which was converted into bone. M. Andral likewise found in one part of the thickened walls of a varicose femoral vein a very hard concretion, of the size of a small nut, formed by a deposit of phosphate of lime†. M. Otto, after alluding to various other authors who have observed ossification of the coronary veins, vena portæ, the brachial vein, &c., states that he has never himself met with ossification of the veins, but that he saw, in the Museum of Pathological Anatomy at Vienna, a splenic vein, a vena portæ, the brachial and femoral veins of an old man and woman, and also, in the Veterinary School at Munich, the preputial veins of a horse ossified‡.

A PROFESSIONAL TOUR IN ITALY;

WITH AN

*Account of the Universities, Hospitals,
&c. &c., of that Country.*

BY M. ROUX §.

BEFORE I enter on the details of my Italian journey, I have some observations to make, of a general nature, respecting three principal topics—namely, 1. The institutions; 2. The men; and 3. The practice of the profession in Italy.

My tour was confined to the northern parts: particular circumstances prevented me from visiting Genoa and Turin; and I shall only speak of what I saw.

The medical institutions of Italy are of three kinds:—1. The academical assemblies; 2. The universities; and 3. The hospitals.

* Hodgson's Treatise on Diseases of Arteries, &c. p. 521.

† Andral, Précis d'Anatomie Pathologique, t. ii. p. 411.

‡ From the Cyclopædia of Practical Medicine.

§ From a paper read by him before the Académie de Médecine, November 18, 1834.

* Anatomie Générale, t. ii. p. 404.

† Morgagni, letter lxi. art. ix.

‡ Transactions of a Society for the Improvement of Medical and Chirurgial Knowledge, vol. i. p. 134.

I have had no opportunity of attending any academic assembly during my tour—a circumstance, no doubt, owing to the period of the year at which I travelled: and even though I had, I should scarcely be inclined to expend criticism on the subject. I never derived much information from meetings of the kind; and remarks on medical societies might be deemed satirical in presence of the assembly before which I speak.—(Laughter.)

The UNIVERSITIES embrace a complete education in all the sciences. We have but one in France. In Italy there are as many as there are different states, and sometimes a plurality in the same state. Thus at Pavia there are two: and they are all perfectly independent of each other. It is remarkable, that in the Lombardo-Venetian kingdom there are few of them; indeed but two; while in the Papal states there are seven, and two or three in Tuscany. Florence, indeed, although the capital, has no university properly so called; yet it is a seat of education more fruitful than either Pisa or Sienna, which have each their separate university. There is this condition, however, attaching to the Doctors of Sienna and Pisa, that they are obliged, in order to obtain the free exercise of their art, to spend several years at Florence, and even to undergo some new tests of skill there.

Each university comprehends four faculties; of which medicine and pharmacy are one. The faculties of Pavia and Padua are the most flourishing. Bologna, which for some years rivalled both in the number of students, has latterly, in consequence of political events, seen its faculty dismembered; one part of it being transported to Ferrara: and the number of students has diminished owing to this circumstance—that strangers are no longer admitted. No university among them all, is to be compared with the single faculty of Paris; for none of them, with their whole four faculties included, can muster more than from 1500 to 1800 pupils, nor more than 400 in medicine alone.

Education.—The course of education nearly resembles that of France. In some respects, indeed, they have departments which we have not, and *vice versa*. Thus in Italy they have not a chair of general pathology and therapeutics, or of hygiene, as we have; but for a con-

siderable period they have had numerous clinics of midwifery, and there are chairs of ophthalmology established in the Lombardo-Venetian universities.

The establishment of these chairs is owing to the enthusiasm inspired into many Italian hearers who attended the celebrated Jaeger, at Vienna, and who were convinced by him of the utility of having them specially endowed. I must confess, however, that previously to my visit I was opposed to such special arrangements; nor has my opinion been altered since: in fact, I am more than ever persuaded that there is no advantage whatever to be derived from them.

The business of each course is marked out by a text (*un texte*). I know not whether the professors do more than comment on the works so singled out (a very faulty practice), or whether they allow themselves a more liberal scope. For several classes the instruction is founded entirely on French works.

The Profession.—There are in Italy three grades, or orders, of medical men: Doctors of Medicine and Surgery, Masters in Surgery, and the inferior class of surgeons, corresponding to the *Officiers de Santé* in France. The period of study for each grade is different: three years only are required for the lowest class, four for the Masters in Surgery, and five for the Doctors.

In all the scientific towns there are beautiful collections, well endowed, and well attended to; and the more so according as the universities are complete. The finest collections are those of Bologna and Florence. Each cabinet, however, has its own peculiar attraction. Pavia would be my favourite for anatomy generally, and for human anatomy in particular. Florence, again, is distinguished above all its rivals by the excellence and beauty of its wax works; its perfection in this branch is carried to an astonishing degree, even in the minutest details. Yet these models in wax are far less wanted in Italy than in France; for practical anatomy, which is rather on the wane among us, is every where held in high favour in Italy. Dissection is practised every where; and I observed one custom which appears excellent;—the pupils of the first and second year are not allowed to touch the dead body; they only *assist* at the dissections.

The collections illustrative of natural

philosophy are capital in Florence. The people there are proud of their Galileo, and have a particular museum with that view.

I should leave my sketch of the state of things in Italy incomplete, did I not express my satisfaction in observing how much honour is bestowed on the illustrious men who have advanced our art; their monuments, their pictures, busts, inscriptions, &c. are every where to be seen. Thus at Padua, Fabricius ab Aquapendente, and Morgagni; Scarpa at Pavia, &c. are held in solemn reverence. It was, however, with pain that I saw at Pavia certain parts of the body preserved: I was both grieved and shocked when I was shewn the head of Scarpa undergoing the process of maceration, steeped in a vessel with other anatomical articles.

One fact regarding Scarpa is not generally known in this country. His body was opened after his death, conformably with his own request; and the head having been cautiously examined, there was found a remarkable alteration in the corpora striata. Now, for several of the latter years of his life, Scarpa, though in the full possession of his intellectual faculties, had lost somewhat of his power of recollecting proper names.

The HOSPITALS of Italy, as they are in all civilized countries, are well supported. On this head I shall only offer a few remarks, without either censure or praise, touching merely on a few of those points in which their hospital system differs from ours.

Almost all the Italian hospitals have been erected for the particular object for which they are designed: thus their structure is in accordance with that object. In nearly all of them the wards are disposed crossways, and are vast and airy. The clinical wards, however, are not so well arranged; they are very small, and very low. At Milan the architecture is superb, the wards very well distributed, and the hospital can contain from 1700 to 1800 patients, without the least apparent inconvenience.

In France we do not admit privileged patients, nor do we keep private wards and chambers. In Italy, however, there are every where found privileged and reserved wards,—an arrangement which seems to me beneficial for the treatment of patients who are able to pay, and who may wish for the attendance of men on whose skill they can rely.

There is no hierarchy (*hiérarchie*) in the French hospitals among the medical men in attendance; but in every part of Italy, the titular physicians and surgeons are attended by other medical men, ready to take their place in case of need; and there is always a physician or surgeon in chief, who enjoys a certain pre-eminence. In France, not only are the hospital physicians and surgeons independent of each other, but in no respect responsible for their actions. Whenever they consult one another, it is matter of pure courtesy. In Italy, the custom—the rule, is, to assemble in consultation, and at this *réunion* he presides who is at the head of the establishment; for in every hospital there is a medical man who holds the rank of director, or intendent, or superintendent. This custom appears to have certain advantages, particularly in surgery.

In France, the sisters (*Sœurs*) have a certain power, which they may sometimes be tempted to abuse. In Italy, devout country as it is, there are no sisters in the hospitals, with the exception of a few who are exclusively left in charge of female patients.

Finally, there are in every French hospital several persons possessing authority of a limited description, but always ready to tread on each other's heels as they proceed in the discharge of their functions. In Italy, there is one principal source from which all the arrangements emanate; and this principal authority is the physician, who is entitled the Director. He is usually chosen from among the elder physicians, and exensed from medical practice. Most of these functionaries are very distinguished physicians.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

A Treatise on Tubercular Phthisis, or Pulmonary Consumption. By JAMES CLARK, M.D. F.R.S. (From the Cyclopædia of Practical Medicine.)

So considerable have been the accessions to our information regarding tubercular phthisis, of late years, that the mere compilation of a compendious treatise on the subject were a task requiring no

small diligence and ingenuity. But we think we may compliment the author of the present performance on having accomplished something more: he has not only given us a clear and comprehensive view of the opinions of all the eminent authors who have, up to the present time, treated of pulmonary consumption, but has interspersed a great deal of original matter derived from his own extensive practice and observation.

The arrangement adopted by Dr. Clark is sufficiently practical. Having devoted some preliminary sections to the ordinary and more obvious characters of the disease, he passes on to the pathological considerations connected with his subject: the statistical history of phthisis is then noticed very interestingly; after which he treats of the causes of the malady, and concludes with an ample and masterly account of the treatment, both preventive and curative, which he thinks it most proper to recommend.

In the section relating to tubercular disease in animals, there is a very curious notice of its probable occurrence even in the insect tribe, which we must extract:—

“Our friend, Mr. Newport, a comparative anatomist of great promise, whose name is already favourably known by his researches into the minute anatomy of insects*, has favoured us with an account of what he believes to be the tuberculous deposits in that tribe. In the larva of the sphinx ligustri, or common privet moth, he met with a peculiar matter disseminated in small, irregular, aggregated masses, white, opaque, and of a cheesy consistence, over the whole internal surface of the insect, between layers of very delicate cellular tissue. These masses were most numerous among the muscles; on the exterior of the alimentary canal, particularly the stomach; on the secretory silk glands, in the biliary ducts, and on the nerves. In the carabus catenulatus, or ground beetle, and in the staphylinus olens, both carnivorous feeders, he noticed similar deposits of more uniform and much smaller size, in the cellular and pulmonary tissues: he has also detected appearances similar to those observed in the sphinx ligustri, in the

common cray-fish, the astacus fluviatilis of Leach. It is worthy of remark, that the sphinx was fed upon stale leaves of the privet for some days previous to examination, the unusual wetness of the season having prevented a fresh supply. The deposition of the same matter has also been produced by purposely feeding the insect upon deteriorated or stale food.

“Although the existence of tuberculous disease in insects requires to be established by more numerous observations than have as yet been made, still the view which we take of the pathology of tuberculous disease inclines us to believe that no class of animals is exempt from it; we therefore have little doubt that the application of the causes which led to it in the human species will also induce it in any animal which is exposed to their influence.

“All the milch cows in Paris become tuberculous after a certain period of confinement to the house. We have been informed that for some time after the disease has commenced, the quantity of milk obtained from them is greater than before, and their flesh is more esteemed by the unsuspecting epicure than that of the healthy animal. A circumstance of the same kind is mentioned by Aristotle, who observed tubercles in a pig, the ox, and ass. He says, in regard to strumous pigs, that when the disease (*grandines*) exists in a slight degree, the flesh is sweeter (*caro dulcior est*). Historia Animalium, lib. viii. cap. 21.”

One or two passages relating to the hereditary transmission or origin of phthisis, may not be uninteresting to the reader:—

“That pulmonary consumption is an hereditary disease,—in other words, that the tuberculous constitution is transmitted from parent to child, is a fact not to be controverted; indeed, we regard it as one of the best established points in the etiology of disease. But it may not be so generally admitted, that various other morbid states of the parent produce the predisposition to tuberculous disease in the offspring; a position, however, which we hold to be equally true, and still more important in its consequences. A parent labouring under tuberculous cachexia, entails on his offspring a disposition to the same affection, proportioned to the degree of dis-

* See his papers on the *Sphinx Ligustri*, in the Phil. Trans. 1833 and 1834.

ease under which he labours. Examples of this fact are constantly present in the families of scrofulous parents, where we find the scrofulous constitution much more strongly marked in general in the younger than in the elder children. We even occasionally meet with families the first children of which are healthy, while the last are the subjects of tuberculous disease; the health of the parents having undergone a change during the increase of their family. There may be exceptions to this rule, depending on circumstances beyond our cognizance, but we have little doubt that it is generally true.

"It may appear that we are disposed to generalise too much, in ascribing tuberculous disease in the offspring to morbid conditions of the parent; nevertheless, we have not formed our opinion upon superficial observation, nor without mature consideration; and we feel persuaded, that the more carefully the subject is investigated, the more correct will our views be found. We have frequent opportunities of remarking a strong disposition to this disease in the children of parents who enjoy what is usually termed good health, and in whose family no scrofulous taint can be traced; whereas, according to our own observation, we never see the parents in an unhealthy state, whatever the nature of their disease may be, without finding, at the same time, that the children are strongly predisposed to tubercles. An opinion is entertained, that one generation sometimes escapes tuberculous disease, although their parents and children suffer from it. This is to be explained by the improved state of health enjoyed by the generation exempted, and by the other circumstances which counteract or prevent the development of tubercles."

Dyspepsia in the parent, the author thinks, is the most fertile source of cachexia of every form in the offspring; shewing itself in a decidedly tuberculous constitution, where no such state had previously been known in the family. Other circumstances likewise, though not perhaps so evidently, may hereditarily excite the strumous diathesis in children; for we often see the latter presenting the characters of the scrofulous diathesis at the earliest age, while the parents are in the enjoyment of good health, and free from all appearances of tuberculous disease, local or

constitutional. "Some remarkable examples of this kind," says Dr. Clark, "have come under my observation, where whole families have fallen victims to tuberculous consumption, while both parents have not only enjoyed good health themselves to an advanced age, but have been unable to trace any hereditary disposition to the disease in their families for generations back."

Among the measures of *prevention*, we find the following valuable remarks relative to the *exercise of the pulmonary organs themselves*: a source of safety for the phthisically inclined, which is usually but too much neglected:—

"Dr. Autenrieth, of Tübingen, according to Sir Alexander Crichton, first recommended the practice of improving the narrow and contracted chest by deep and frequent inspirations. He advised his patients to place their hands upon some solid support, and to exercise themselves by taking repeated deep inspirations; but cautioned them against carrying this so far as to produce pain. We are in the habit of recommending the full expansion of the chest in a manner somewhat different from that of Autenrieth; we desire the young person, while standing, to throw his arms and shoulders back, and while in this position, to inhale slowly as much air as he can, and repeat this exercise at short intervals several times in succession: when this can be done in the open air, it is most desirable, a double advantage being thus obtained from the practice. Some exercise of this kind should be adopted daily by all young persons, more especially by those whose chests are narrow or deformed, and should be slowly and gradually increased. Fencing, the use of dumb-bells, and similar modes of exercising the arms, will also be eminently useful in attaining the important end we have in view; but they should never be carried so far as to induce fatigue or uneasiness. If regularly employed by boys under this necessary restriction, they would not merely expand the chest, but would tend to remove that disproportionate development of their upper and lower extremities which we so frequently observe in youth. By thus exercising the upper extremities, and the muscles of the trunk, and inflating the lungs to their full extent, the chest and pulmonary organs will acquire their due proportions.

We also consider exercises of this description particularly necessary to persons engaged in occupations which require a bent or stooping posture; and especially to those mechanics, as tailors and shoemakers, whose constrained position seldom allows the upper parts of the lungs to be fully expanded.

"Reading aloud and public recitation, will also, when prudently employed, be useful in strengthening the pulmonary and digestive organs, and in giving tone and power to the voice. The clear and distinct enunciation, which is acquired only by long practice, is seldom found associated with pulmonary disease, and we are therefore inclined to commend the practice of recitation and elocution at schools. It would, we believe, be difficult to cite the example of any great orator who died of pulmonary disease, while many might be adduced whose health was improved and their life prolonged by the beneficial effects of this exercise. Cicero was disposed to phthisis in early life, and Cuvier attributed his exemption from pulmonary disease, to which he was expected to fall a sacrifice, to the increased strength which his lungs acquired in the discharge of his duties as a public lecturer."

Perhaps a better illustration of the healthiness of the practice of public oratory, and of its conduciveness to longevity, could not be afforded, than in the case of the late Mr. Thelwall, who, though a person of slight figure and *physique*, and little used to tranquillity in the habits of his life, attained an age considerably beyond the period allotted to man, enjoying to the last the most powerful energy of voice and action. He was the only person, in recent times, who taught and practised the art of oratory on true physiological principles.

The Medical Pocket-Book for 1835. Containing a Case-Book and Almanack, &c. &c. By JOHN FOOTE, Jun. Renshaw.

REALLY a very useful little book, containing an abstract of every thing in the world—that is, in the *medical* world. Particulars of our corporations, societies, medical schools and universities, at home and in France; a pharmacopœia, new medicines, London bankers, hackney-coach fares, and Halley's comet:

quite a *multum in parvo*. In one respect, however, the *parvum* is too conspicuous—we mean the portion allotted for cases; which would require a Lilliputian to write in it. We would recommend that the alternate page, devoted, or rather intended to be devoted to this purpose, be hereafter assigned merely to the names and addresses of the patients: this purpose it might answer, by making the two pages facing each other represent one week, and leaving larger spaces for each day. With this change it will be more useful; nevertheless we recommend Mr. Foote's new year's gift to our readers.

The Principles of Ophthalmic Surgery; being an Introduction to a Knowledge of the Structure, Functions, and Diseases of the Eye; embracing New Views of the Physiology of the Organ of Vision. By JOHN WALKER, Assistant-Surgeon of the Manchester Eye Institution.

AN exceedingly concise and comprehensive little volume. It takes in all the chief facts relating to the structure and functions of the eye, as well as every thing really valuable connected with the treatment of eye disease. In the shape of an appendix, the author gives an excellent glossary of all the terms generally employed in ophthalmic surgery, with their etymology, and German and French synonyms. His "new views" of the physiology of the eye require no particular announcement from us, for they must be familiar to the readers of this journal, in which, either at length or in substance, they were originally published by the author himself.

MEDICAL GAZETTE.

Saturday, Nov. 29, 1834.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

EVIL OF DISPENSARIES, AND HOW IT MAY BE CHECKED.

THERE are two modes in which an immense number of persons in this coun-

try, but more particularly in the larger towns, procure medical attendance gratuitously—namely, by application to their respective parishes, and to dispensaries. Both of them are in various respects objectionable, as we have endeavoured on repeated occasions to demonstrate—degrading the parties relieved, by destroying their sense of independence, and injuring the medical profession, by depriving them of a very large sum annually, which would otherwise accrue, from persons perfectly able to pay, but mean enough to prefer the cheaper expedient of applying to a neighbouring “charity.”

That the parish surgeons are generally over-worked, and under-paid, is notorious; but we fear that with them, as in the case of dispensaries, much of the evil arises from the extent to which the spirit of competition is carried—a spirit which too often degenerates from a fair and commendable rivalry, into a wretched system of mutual injury, by underselling each other till the remuneration at last received be utterly unworthy any man of liberal attainments to accept for his services—scarcely more, in fact, than a ploughman would earn by his labour, and certainly less than many an “operative” can easily obtain by the fruits of his handicraft.

Again, as to the dispensaries, we readily admit their utility within certain limits, but we cannot too strongly reprobate the extent to which they have been carried. In the metropolis (with which we are more intimately acquainted) it is within our personal knowledge that petty tradesmen in the neighbourhood of such institutions frequently become subscribers from purely mercenary motives, contributing twenty shillings, and twice as many patients, annually to the “charity,”—the facility, if not the positive privilege, of obtaining dispensary letters, being held out as a bonus

to their customers;—nay, we have known letters of recommendation actually sold for a mere trifle, and, especially when so obtained, used by the parties who have purchased them with all the exacting arrogance which the vulgar are wont to display on claiming what they consider to be a right; so that the attendance of a physician or surgeon, or both together, with medicines and all appliances and means to boot, are demanded (*or commanded*), for the moderate sum of sixpence sterling! Hundreds and thousands of persons are thus annually relieved, who unquestionably ought, and who otherwise would per force become the patients of the general practitioner, by whom no inconsiderable emolument would thus be fairly derived, from means which are now, by injudicious charity, diverted to the gin-shop, or the haberdasher's, to pamper the appetites, or to feed the vanity, of the undeserving. This may seem harsh, but we speak, as we have said, from a personal knowledge of the facts; and we scarcely think that we can too strongly oppose a system which, by the indiscriminate supply of relief, brings charity itself into discredit.

One of the most direct and least objectionable methods of obviating these great and growing evils, appears to present itself in the substitution, for common dispensaries, of those which are called “self-supporting;” and it is a conviction of the importance of the subject to the members of our profession, as well as to the public at large, which has induced us still to persevere in urging it on their attention. Another consideration which likewise weighs with us, is the desire to correct what it appears is an erroneous supposition, promulgated in a recent number—namely, that no institution of this nature existed in the metropolis. An

intelligent correspondent has put us right in this respect, and has furnished us with some satisfactory and important information relating to a successful experiment which has been made in the "North-west London Self-supporting Dispensary." The general plan adopted is a close imitation of that which has proved so advantageous at Coventry; and a like fate, we trust, awaits it here. It is no less gratifying to us, who have early and earnestly advocated the system, than it is creditable to the parties themselves, to find that this truly enlightened and patriotic scheme, of teaching those whose means are small to be provident, and of securing to them relief undegraded by charity in the hour of sickness, has already attracted the notice, and received the patronage, of the Bishop of London, and several noblemen and gentlemen of distinguished benevolence. Encouraged as it has been by the countenance, and aided by the contributions, of such friends, there is every reason to hope that the experiment may prove successful. But a still more cheering assurance of the issue is to be found in the fact, that not fewer than 350 of the industrious among the class of operatives, servants, and labourers, have already become subscribers, contributing their weekly mite towards the general sum. An address, with the view of explaining the objects, and inducing persons to become members with a view to future benefit, has been extensively circulated, and appears to us extremely well adapted to its purpose. The following is an extract:—

"The advantages offered by the Self-supporting Dispensary are the following:—

"I.—You will have tickets of admission constantly by you, which will enable you to procure medical assistance without any trouble or loss of time.

"II.—You will be saved the humiliation of *begging* a charity letter.

"III.—You will be spared the degradation of applying to the parish.

"IV.—You will be prevented from incurring debts which may be hard or even impossible to pay, and your minds in sickness will not be troubled with the fear of a doctor's bill.

"V.—You will have no need to apply to ignorant persons or to take quack medicines, which often seriously injure the health, and cost more than the whole year's subscription.

"VI.—You may choose your medical attendant, and if your case be a difficult one, you may have the other physicians and surgeons to consult together about it.

"To gain all these advantages you have only to pay your weekly penny, which scarcely any are too poor to afford, when in health.

"Thus the calamities of sickness, which may come upon yourselves or families at any time, will be lightened, and under the blessing of God, removed, whilst your own industry and foresight will preserve you in a state of honorable and praiseworthy independence."

A more detailed prospectus, addressed to persons of a higher class, who may be expected to become honorary contributors, has also been sent to us, and has our entire approbation: from this also we subjoin a short extract, explanatory of the principles and the plan on which the institution is founded.

"The institution is supported by two distinct funds,—the *honorary* and the *ordinary* fund.

"The honorary fund is derived from the subscriptions and donations of the benevolent, and is applied to defray the expenses of the establishment and the dispenser's salary.

"The ordinary fund consists of the small periodical payments of the poor subscribers (one penny a week for each adult, and one halfpenny for each child, or one penny for all the children of a family, where there are more than two), and is devoted to the purchase of drugs, and the remuneration of the ordinary medical attendants.

"Before persons can be admitted to the benefits of the institution as ordinary subscribers, their circumstances are investigated by the secretary and a

sub-committee, to ascertain that they really belong to that class for which the institution is formed. The proceedings of the sub-committee, as well as the general business of the institution, are under the direction of the committee. The power of controlling the committee, of altering or making laws, and of electing or removing officers, is vested in the governors (donors of ten guineas, or annual subscribers of one guinea), who meet once a year, or oftener, as circumstances may require.

"The following are the prominent advantages which the Self-supporting Dispensary offers:—

"I. To the public generally:—

"By promoting among the industrious classes habits of prudence and forethought, and by providing them against the contingencies of illness, which now are continually and unavoidably increasing the burthens on public charity and parochial expenditure.

"II. To the individuals subscribing:—

"By enabling them to procure promptly, in the way most pleasant to their feelings, and most consistent with their means, efficient medical advice and medicine, and thus to maintain their station through the trying times of sickness, in honest and praiseworthy independence.

"III. To the medical profession:—

"By freeing practitioners in general from those calls on their time and services for which there is little chance of payment in the usual way, and by securing to the ordinary medical officers of the dispensary a moderate remuneration for their time and services.

"IV. To existing dispensaries and other charities:—

"By relieving them of many applicants who cannot be considered legitimate objects for gratuitous relief, and thus enabling them to extend their benefits to a larger number of the really helpless poor."

With regard to the third party here mentioned, whatever may be the feelings of others, we have no doubt that any change must be good which frees the medical profession from the unjust

and most oppressive tax of attending a number of improvident and unprincipled among the poor, who demand their services with all the authority which the professed intention of paying bestows, but who, when the hour of their trouble has passed away, forget their just debt—or at least postpone their payment of the "Doctor" till every other demand upon them has been answered; strengthened in their contumacy by the too easy indulgence with which medical men almost uniformly treat their debtors. This is no imaginary, nor even a highly-coloured picture. The thankless and profitless, but most wearisome labours of some of our profession, among the lower ranks in London, are neither known nor appreciated by society at large; and well assured we are that it is an evil which cries loudly for abatement. We could name a general practitioner, residing in a densely populated district, who toils incessantly at his useful but ill-paid vocation. Last Christmas he sent out bills, chiefly among the petty tradespeople and artisans, to the amount of 800*l.* the total of his just and hard-earned profits: of this sum, (the whole of which would have afforded but a very moderate recompense for his time and medicines) he had actually received at Midsummer the miserable dole of 130*l.*; nor did he expect to obtain more than another hundred pounds, even with all the mortifying expedients of dunning, or the still more vexatious appliances of the law.

We have heard that some general practitioners object to the system of self-supporting dispensaries, and we are most sincere in saying that there are few things we should be more unwilling to undertake, than the support of any cause calculated to do them injury: but we do not see how such effect can result from a system which has for its very basis an acknowledgment that, at all

times, "the labourer is worthy of his hire;"—a system which renders those very persons who now demand his attendance, and deny his recompense, familiar with the necessity of being provident, and accustoms them to contemplate the remuneration of the medical practitioner as a reasonable and familiar constituent in their expenses. To us it certainly appears that the evil to those who practise among the persons who alone would become members of a self-supporting dispensary, cannot well be increased—that any change must be a change for the better. Influenced by these views, we again repeat, that if zealously and faithfully administered, the new institution which has called

forth our present observations can scarcely fail ultimately to succeed, and that meantime it has our best wishes for its prosperity.

ANATOMY IN ITALY.

Two things seem to have particularly struck M. Roux in his late Italian tour—the respect every where paid to the memory of departed greatness, and the arduous evinced for the pursuit of practical anatomy. Of both, however, he had rather an unpleasant proof in one instance. He was shocked, he says, at Pavia, *to see the head of the illustrious Scarpa actually undergoing the process of maceration, in a vessel along with other anatomical preparations.*—(See p. 308.)

UNIVERSITIES OF PRUSSIA.

WE extract from the official returns published at Berlin in the present year (1834), the following statistical statement:—

Universitäten.	Total number of Students.	Medical Students.	Ordinary Med. Professors.	Extraordinary Med. Professors.	Privatim Docentes.

Münster ...	292	0	0	0	0

MEETING OF STUDENTS OF THE LONDON UNIVERSITY.

THE LANCET, AND THE LATE REGULATIONS OF THE COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

A VERY imperfect account of the late meeting of the Students at the London University, on the subject of the new regulations of the College of Surgeons, having appeared in the last number of the *Lancet*, and this account being calculated, in the opinion of several of the students, to do considerable injury to their character as a body, I beg to re-

quest your insertion of the following statement, for the correctness of which I pledge myself.

A notice was issued at the close of last week, calling upon the students to meet on Monday, the 20th, "to express their detestation of the tyrannical regulations lately issued by the College of Surgeons." This notice was anonymous. The students assembled at the time appointed; and it was evident that the majority came, not from approving the object of the meeting, but because they did not wish that any proceedings should go forth to the world, as emanating from their body, which might in reality express the opinion of a very small part of it. No one seemed ready

to open the business of the meeting; and the question was at length asked, by whom it had been summoned, on which Mr. Thomson* stated, that he was one of six who had agreed on issuing the notice; and he was accordingly requested to take the chair. Mr. T. was then asked whether he had not gone to the Editor of the *Lancet*, to request him to be present at this meeting, to which he (Mr. T.) replied, that he had gone with others to Mr. Wakley, to inform him of the meeting which was to take place, and to request him to send a reporter. Mr. T. then explained his object in calling the students together; and as it was evident that he had taken the exposition of the new regulations given by the *Lancet* as the ground of his opposition to them, several individuals, myself among the rest, pointed out the gross mis-statements which had been made in that journal respecting them. It was then moved that "it is inexpedient that this meeting should give expression to any opposition to the new regulations;" and this proposition appeared to coincide with the wishes of the great majority of students present. It was, however, violently opposed by a gentleman, whose speech is given at full length in the columns of the *Lancet*, but of which only about *two sentences* were actually delivered,—so much laughter and disturbance being excited by it, that the chairman, after in vain attempting to restore order, vacated the chair, which Mr. Chippendale was then requested to take. The motion was soon afterwards put, and carried by a very large majority, only about six hands being held up against it. Of the remainder of the meeting, I am sorry that but too true a picture is given in the columns of the *Lancet*. The vote of censure which was proposed on those individuals who had summoned the students together, emanated from a very natural feeling of anger, that so much time should be lost in attending a meeting for which no business was prepared.

I will now, with your permission, venture one or two remarks upon the regulations which have been the source of so much misrepresentation and unpleasant feeling. By the first, every

student, on the commencement of his education in London, is required to register at the College the amount of his previous studies, if any, and also to produce evidence of having entered to those studies which are necessary to complete his education. No student can, I presume, object to the first part of this regulation, as the same form has long been required by the Apothecaries' Company, and has never been made the ground of any complaint. I confess that I do not know in what sense to understand the second part: if taken in its literal sense, it certainly would press rather heavily on the student; but I presume that it has been either completely misunderstood, or that it has not been put in practice, as I am not aware that any students have been asked what lectures they have entered to in London, that register being made by the teachers of the different schools. It is to be regretted that some uncertainty exists among the students, as to whether it will be necessary to have the certificates already obtained re-signed upon the form now prescribed by the College, various answers having been given to this question, when put by different individuals.

With regard to the second regulation, no objection can of course be felt by the students to the mere registration and quarterly return which is required from the teachers; but the system of *espionage*, as it has been termed, which is imposed on the teachers by the latter part of the regulation, ought, I should think, to meet with more opposition from those gentlemen themselves, than from the students. I cannot see how a lecturer, with a class of say 200, can form a correct estimate of the degree of diligence of each individual; whilst, on the other hand, I do not see why a diligent student should object to such an account being kept, though I think you will agree with me, that the regularity of attendance on lectures is by no means the only criterion of a student's diligence and anxiety to improve.

In conclusion, I would beg to suggest to my fellow students, that the Council of the College of Surgeons is composed of *gentlemen*; and being so constituted, is not likely to put forth any regulations deserving the epithets of unjust or oppressive; and that they can act far better than by submitting to

* I have no hesitation in giving this gentleman's name, as it has already appeared in the *Lancet*.

be led by a small faction who, for their own purposes, endeavour to excite discontent in the general body.

Hoping that I have not trespassed too long on your valuable columns, I beg to subscribe myself

Your obedient servant,

A STUDENT AT THE LONDON
UNIVERSITY.

November 22, 1834.

[The writer of this letter has given us his name.—ED. GAZ.]

HOTEL DIEU, PARIS.

Curious Case of Viper-bite—Alarming Symptoms—Recovery.

THERE is at present, in this hospital, a case, such as is rarely met with in Parisian practice;—a patient who has been bitten in the metropolis by a viper, and who has exhibited all the extraordinary symptoms to which such an accident is usually said to give rise.

Giraldon, a quay porter, aged 30, was occupied, on the 31st of October last, in depositing some bundles of faggots at the Pont Neuf, when out of one of them dropped a benumbed viper. He took it up in his hands, warmed it, and amused himself with it for five and twenty minutes without any mischief. He then took the reptile home with him in a box, and put it beside the stove. Next day, towards noon, he was informed that vipers were sold, and he was inclined to make some money by his; so he took the box under his arm, and, accompanied by a friend, proceeded to the *Marché des Innocens*. On the way he went into a wine-shop, and, wishing to make a parade of his capture, turned the viper out of the box on the counter. The cold of the zinc gave the animal some annoyance, so that it moved briskly about, and writhed itself round a bottle. The by-standers became alarmed; but Giraldon, anxious to get the viper into the box again, seized it with his right hand. He was bitten in a moment, on the second phalanx of the little finger.

In spite of the sharp pain he felt, he persevered in his object; and being unable to shake it off, seized it by the neck and tore it away. Still he was determined to sell his viper, and, putting it in his pocket, proceeded towards the market; but he had not gone far when he felt so unwell, with sickness of stomach, tottering limbs, and confusion of head, that he was obliged to

sit down on some steps. His hand was visibly swollen. At this time, no more than five minutes had elapsed since the bite.

Supported and almost carried by his friend, he reached the shop of a *pharmacien*, who enlarged the wound and put some drops of ammonia into it, administering also some of the same remedy internally. The cauterising of the wound was very painful, and caused the patient to faint away. He was likewise affected with frequent vomiting. When he was brought home and put to bed, a violent tremor seized him. His arm, in the course of an hour, had become double its natural size; his chest and his neck swelled in the evening; he was insatiably thirsty, vomited constantly, and suffered violent colic pains, with diarrhœa.

On the following day, Sunday, Nov. 2, twenty four hours after the accident, he was attended by a medical man, who tried mercurial frictions on the arm, and made him take a potion having ammonia in it. But the symptoms becoming more and more serious, he was taken on the day after (Nov. 3) to the Hôtel Dieu, where, on admission, his state was described as follows:—The hand, arm, and forearm, are tense, three times the ordinary size, red, and painful; all the inner side is ecchymosed, and even denuded of the cuticle; phlyctenæ are observed on different parts of the hand. On opening the wound to the extent of half an inch, it appears greyish at the bottom, and presents an eschar, probably the result of the cauterisation. The chest and walls of the abdomen, down to the navel, are considerably swollen, elastic, and not preserving the impression of the finger.

The patient was now in a state of prostration: the tongue blackish and dry at the point; the teeth dusky and foul. He felt an undefinable uneasiness at the pit of the stomach, with general pains. A constant desire to vomit; with colics and diarrhœa. He was, in fact, in so alarming a condition, that all the medical men expected the worst. Their expectations, however, have not been fulfilled: the man may be at present considered as out of danger.

The remedies employed, we are inclined to think, had but very little to do with the cure, and the patient would probably have got well without them. They consisted simply of emollient fomentations to the arm; a draught with ten drops of ammonia, on the first day of his admission, which only aggravated the vomiting, and had to be discontinued afterwards; twenty grains of ipecacuan, which seem to have had no effect; and lastly, twenty leeches to the pit of the stomach, in consequence of the

pain felt in that spot. It is evident that there was no distinct line of treatment adopted.

On the whole, we cannot refuse assent to the opinions of MM. Merat and Fontana, that the bite of a single viper is inadequate to take away a man's life, and that the effects which it produces, however alarming they may appear at first, are all gone by the fifth or sixth day.

The patient, for the last four days, has been nearly quite well. His chest is no longer swollen; he eats and drinks, and is in good spirits. The arm alone is still ailing*.

ON THE NATURE AND TREATMENT OF SUSPENDED ANIMATION.

WHATEVER be the suffering which precedes what is called death, the moment of that death is but its termination, but the conclusion, as far as our feelings are concerned, of the process of dying. As soon as disease is established, the act of dying is begun, and we have no reason to believe that, as far as the body is concerned, its nature is in any respect changed in what is called its termination. It is, from the first to the final ceasing of all the functions, a more rapid than natural decay of the powers of life, with, while sensibility lasts, more or less suffering, according to the cause which produces it. In recovery, our suffering terminates by the removal of that cause; in what is called death, by our becoming insensible to its effects; the bodily process being in no other way influenced by our total insensibility, to which the name of death is applied, but that the consequent ceasing of respiration accelerates it.

The body at this moment can no more be regarded as in the act of dying than at any other period of the disease; and the removal of the offending cause will not only in many cases at this period, if proper means be employed, but in some, even a short time after it, be followed by recovery. Thus, even after the period at which, according to the common meaning of the word, the process of dying is completed, it is, under certain circumstances, not too late to arrest that process, and restore the sufferer to the perfect enjoyment of his faculties. Recovery may take place after respiration has, from submersion, for a few minutes ceased, and the sufferer is, in the common acceptance of the term,

dead, his sensibility, and consequently his respiration, independently of artificial means, being finally extinguished.

That this may happen, it is necessary not only that the vital system should have been just before in a state of healthful vigour, but also that the respiration should not have failed from the failing sensibility, but the operation of the offending cause. Here the sensibility fails from the failure of respiration, not, as in other cases, the respiration from the failure of the sensibility; but this difference in the succession of events makes no difference in the general nature of the actual state induced.

The recovery depends on our being able, more or less perfectly, to restore the function, the failure of which has caused the failure of all the others, as far as it has taken place, before the process of dying has proceeded too far for the restoration of the sensitive system. If no artificial means are employed, the date of death here is the time at which the sensibility ceased, and justly, because at that time death, according to the common meaning of the word, has taken place. The individual no longer feels and wills.

If there were even the last remains of sensibility, breathing would take place without external aid, as happens when the submersion has not been long enough wholly to extinguish it. The individual has, without such aid, finally ceased to feel and will, and is therefore what we call dead. His blood still continues to move, and all the assimilating processes, as appears from the experiments above referred to, are still going on; but this is no more than happens, more or less, in all cases after what is called death; the only difference being that from the nature of the offending cause, and the short duration of the disease, these functions are in a state of greater vigour than when the loss of respiration has been the effect of the loss of sensibility, which makes no difference in the nature either of their remaining powers or the circumstances in which they are placed, and would not prevent their ceasing, as usual, if no means were employed to arrest the dying process. I have dwelt the longer on this case, because it affords a good illustration of some of the preceding as well as following parts of the subject.

From the experiments which have been laid before the Society (Philosophical Transactions for 1822, 1827, and 1829, and Experimental Inquiry, Part II. chap. xii.), we have reason to believe that the effects of artificial respiration in restoring those whose breathing has been interrupted till the sensibility is destroyed, would be greatly aided by the use of voltaic elec-

* Bulletin de Therapeutique, et Gaz. des Hôp.

tricity sent through the lungs in the direction of their nerves, and that many might thus be restored in whom infiltration of the lungs alone fails. The inflation of the lungs in such cases acts in two ways. It gives to the blood of the smaller vessels of the lungs some of the arterial properties by which they are often excited, and acting through the blood of these vessels, it communicates to that of the larger vessels, and of the heart itself, more or less of the same properties, independently of the blood already changed being moved on towards this organ; for M. le Gallois has shown that after the circulation has permanently ceased, the blood may, to a certain degree, be changed by inflating the lungs, not only in the trunks of the pulmonary veins and the heart itself, but even in the great arteries.

There is reason to believe, from the whole of my experiments, that the lungs should not be inflated more than eight or ten times in the minute, and that the injection of large quantities of air and great force in its injection should be avoided, and consequently the patient placed in the position in which the chest expands with the greatest ease. One of the chief defects of artificial breathing is, that in it the chest is expanded by the pressure of the injected air, whereas in natural breathing the air enters in consequence of its expansion. But the most essential difference between natural and artificial breathing in such circumstances is, that there cannot, till recovery is far advanced, be the proper supply of nervous influence, the due action of the vital parts of the brain and spinal marrow only being restored in proportion as the due force of circulation returns. Now it appears from what is said in the *Philosophical Transactions* for 1822 and 1827, and more fully in my *Inquiry into the Laws of the Vital Functions*, that voltaic electricity sent through the lungs in the direction of their nerves, is capable of performing as perfectly as that influence itself, the part which belongs to it in respiration, which is so essential, that the more perfect animal always dies from impeded respiration if the nervous influence be withdrawn from the lungs, unless a little electricity be supplied, which enables it to breathe as well as when the nervous influence is entire.

A proper apparatus, therefore, for sending voltaic electricity through the lungs in the direction of their nerves and in due power, should be added to the other means of resuscitation, which would render them, and probably to a great degree, more successful. The force of this observation will be perceived when it is considered that it is at the time of the first application of the remedies that the chance

of recovery is greatest, and consequently that the immediate application of the whole means of healthy respiration, as far as we possess them, is of most consequence. It appears from what has been said, that the due functions of respiration cannot be restored till the due degree of nervous influence is supplied, and this cannot happen from infiltration of the lungs till the due force of circulation returns. Now the fact, explain it as we may, is, that voltaic electricity so perfectly supplies the place of the nervous influence in the lungs, that their functions are equally perfect under the influence of either. The one can only be supplied at an advanced period of recovery, that is, in fact, only in those cases where the success of our endeavours can be secured by other means; the other is, in all cases, within our reach on the instant*.

PURIFICATION OF CARBONATE OF SODA.

By M. GAY LUSSAC.

THIS salt is commonly purified by repeated crystallization, but it retains so large a quantity of interposed mother liquor that many operations are required to entirely free it from other substances, and after all but a small quantity is obtained. The following process having appeared to me extremely advantageous, I think it may be useful to make it known.

This process is analogous to that which is followed in France for purifying nitre. It is as follows:—Take the crystals of carbonate of soda, such as are met with in shops; having washed them, make a saturated hot solution; when this is set to cool, stir constantly with a rod or spatula to disturb the crystallization, and to obtain small crystals resembling sand: the cooling may be accelerated by placing the vessel containing the saline solution in cold water. It sometimes happens that when very much cooled, the solution does not crystallize, and that it suddenly becomes solidified. This is the moment to stir very rapidly, to prevent the conglomeration of the crystals. This delay in the crystallization may be prevented by throwing a few crystals into the solution at the moment when it begins to be supersaturated.

Having obtained the crystals, put them into a funnel, in the neck of which place a little tow or cotton to retain them. At first let them drain, then wash them with small quantities of distilled water, waiting till the preceding washing has run through.

* From Dr. W. Philip's *Treatise on Sleep and Death*.

Test from time to time the washings with nitrate of silver, the washings being previously saturated with pure nitric acid: the purification of the salt is complete when the liquid remains transparent. By this process, and in the first operation, the greater part of the carbonate of soda employed may be obtained in a perfectly pure state. The mother liquor and the washing may be evaporated and treated in the same manner. The same mode of purifying may be used with advantage for many other salts. Its efficacy is founded upon the extreme facility with which water runs through and well washes sandy crystals, such as are obtained by disturbing the crystallization.—*Annales de Chimie et de Physique*, and *Dublin Journal*.

ANTI-PSORO-SYPHILIDE.

By this name Dr. Tronein, of Paris, calls a specific which he offers to the world as an infallible means of eradicating all venereal affections, past, present, and to come. The composition of his remedy is as follows:—

Distilled water of Vervain.	_____	root of Asclepias.
_____	_____	roots and bulbs of Alisma Plantago.
_____	_____	Cientia Aquat. leaves,
_____	_____	flowers, and seeds.
_____	_____	Mentha Piperita: aa.
_____	_____	1 litre.

Mix, and pass a current of pure chlorine through them for half an hour; then add,

Corrosive Sublimate.....	48	grains.
Eau de Cologne.....	1	litre.
Essence of Peppermint.....	1	gros.
_____ Bergamot.....	$\frac{1}{2}$	gros.
Oil of fine Aspie.....	$1\frac{1}{2}$	gr. s.
Sulphuric Ether.....	2	gros.

Always shaking the mixture well upon every addition.

The *Anti-psoro-syphilide* is used as a lotion, and a cosmetic.—*Gazette des Hôpitaux*.

POISONING WITH CANTHARIDES.

In the Eighth Annual Report (1833) of the New York House of Refuge, we find the following curious case:—A boy, 17 years of age, in a fit of anger took an ounce of the tincture of cantharides, supposing it to be laudanum. It was soon followed by convulsions of the most violent kind, which, after a few days, left him apparently well. He now had a presentiment that he should die on the succeeding Sunday; and with that idea deeply impressed upon his mind, he fervently exhorted his associates to reform their lives.

His convulsions returned, and he died on the day he had predicted. His last attack was accompanied by the following remarkable symptoms:—During the intervals of the convulsions, and after they had ceased, while he was in a state of perfect insensibility, and volition entirely suspended, his limbs would retain for any length of time the same position in which they were placed by any person present. If they were placed in an erect, or horizontal, or flexed posture, they remained so, perfectly motionless.

LITERARY INTELLIGENCE.

IN THE PRESS.—Observations on the Causes and Treatment of Ulcerous Diseases of the Leg. By Mr. J. Spender, of Bath.

Dr. Prichard's new work on Insanity, and other Disorders of the Mind, accompanied with numerous Cases, exemplifying various descriptions of Madness, is in the press.

BY THOS. DAVIES, M.D.

LECTURE X.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

HAVING thus, gentlemen, described the disease of the aërian passages, we now proceed to those of the parenchymatous substance of the lungs.

The diseases of the substance of the lungs may be subdivided into two sections: 1st. Primary diseases of the pulmonary tissue. 2d. Diseases of the substance of the lungs arising from adventitious deposits. I offer you the following table explanatory of the order we shall follow:—

1. Primary diseases of the pulmonary tissue—

Peripneumonia.
Œdema Pulmonum.
Apoplexia Pulmonum.
Emphysema Pulmonum.
Asthma.

2. Diseases of the substances of the lungs, arising from adventitious deposits. These deposits are—

Tubercles.
Ossific deposits.
Cysts.
Hydatids.
Medullary Sarcoma.
Melanosis.

1st. *Primary Diseases of the Pulmonary Tissue.*

Peripneumonia.—By peripneumonia we mean an inflammation of the substance of

the lungs. Although it is a disease of very common occurrence, yet its morbid anatomy was not well understood until described by Laennec. We shall proceed precisely in the same order which we followed in the first section, and consequently at once describe the morbid anatomy of this affection.

Morbid Anatomy of Peripneumonia.—This subject may be considered under five different stages, or states, most of them having different signs, and requiring different modes of treatment. These states are named, 1. Engorgement. 2. Hepatization. 3. Purulent Infiltration. 4. Vomica; and 5. Gangrene.

1st Stage—Engorgement.—The lung is now heavier than natural; its external colour is livid, or violet, and its firmness is increased: it still crepitates, though in a less degree than in the healthy organ; it feels more compact, and pits upon pressure like an œdematous limb. When a section is made, its surface is of a bright red colour, and a large quantity of sanguineous and spumous serum flows from the incision. The alveolar or spongy texture of the lung is still perfectly apparent: here and there a few firm and compact points may be seen, indicating approaching hepatization.

2d Stage—Hepatization.—The lung no longer crepitates upon pressure, because no air is contained within it; it has acquired the weight and firmness of the liver, and hence the term hepatization.

The colour of the external surface of the hepatized lung is often less livid than in the state of engorgement; internally it varies from violet to a deep blood-red tint. These colours are often so intermingled and shaded, that the cut surface presents the mottled aspect of certain marbles, or granites, and the similarity is rendered still greater by the inflamed lung being spotted irregularly by the black pulmonary matter, looking like small spots of mica disseminated in it. The branches of the bronchi and blood-vessels are seen ramifying over

the surface of the section, and the interlobular cellular tissue becomes more distinct than in the natural state; it is whiter, and does not appear to participate in the inflammation.

There is no exudation from the section of a hepatized lung; but a thick and red-coloured fluid, in which can be frequently distinguished a matter still thicker, opaque, white, and puriform, may be scraped off by a scalpel.

If the hepatized lung be torn, or a thin slice of it be examined by a strong transmitted light, its texture appears granular, and the grains are small, red, round, or ovoid, and somewhat flattened; these are doubtless the air vesicles, rendered solid by the increased thickness of their parietes, and the infarction of their cavities.

When a lung is entirely hepatized, it appears, on a first view, to be increased in volume, but it really is not so: this appearance arises from the solid organ containing no longer any air, and consequently not collapsing on the opening of the chest.

It sometimes happens, especially in children, that small patches of hepatization occur here and there in the lungs, confined to a lobule, the surrounding lobules being perfectly healthy, or only slightly infiltrated. This state is called *Lobular Pneumonia*.

3d Stage—Purulent Infiltration.—The pulmonary tissue preserving still the same firmness and granular structure, as described in the second stage, becomes of a pale or light straw colour. At first, slight yellow spots of concrete pus are disseminated here and there, and render the shades upon the hepatized surface still more varied, irregular, and mixed. These points enlarge, and unite until the whole becomes of a straw colour. A yellow, opaque, viscous, and puriform matter of a faint smell, may be scraped off, and the substance of the lung now becomes more soft and humid, and may easily be penetrated by the fingers. The granular structure finally disappears entirely.

In old persons, the lungs have always a dark aspect; this arises from the quantity of black pulmonary matter contained within them: when, therefore, these organs are in a state of purulent infiltration in advanced life, this black colour, by its mixing with the yellow, gives a grey tint, very different in aspect from the same condition of lungs in young persons. This has been called *grey hepatization*. In adolescence and infancy, the infiltrated concrete pus is of a fine whitish yellow, and, as it softens, an unctuous matter may be scraped off, which has been mistaken for fat.

4th Stage—Fomica, or Abscess.—It is commonly supposed that abscess of the lung is

of frequent occurrence, as a result of peripneumonia: nothing is however more rare. Laennec, during twenty years, only met with five or six instances in many hundred autopsies. My friend, Mr. Langstaff, does not possess in his splendid collection a single specimen. I have met with none, after twelve years' habitude in post-mortem examinations. I here shew you, however, a preparation of this disease, which I found in our museum, and which I believe has been there for many years. No doubt, tubercular excavations have been frequently mistaken for peripneumonic vomicae. I have seen what may be called pseudo-vomicae, formed by an inexpert anatomist, tearing away a lung adhering to the costal pleura, and plunging his fingers into the organ softened by purulent infiltration.

Laennec describes a case in which he found an abscess situated at the middle and anterior part of the lung; its form was elongated and flattened: in proceeding from its centre, the liquid pus changed into a purulent detritus, then into a firmer tissue, still fully infiltrated with pus, and, finally, at half an inch farther the lung was in the ordinary state of purulent infiltration. Andral mentions another instance, in which, towards the middle part of the inferior lobe, there was found a sort of "bouillie," containing in its centre true pus; the pulmonary substance immediately around it was in a state of detritus, and beyond that, of purulent infiltration.

5th Stage—Gangrene.—Laennec has described this disease in a special article: I think it best, however, to place it here, for the sake of arrangement, although it may be considered doubtful whether gangrene is ever a consequence of common inflammation of the lung. It is probable, but not certain, that it is essentially and primitively a gangrenous affection, as anthrax, malign pustule, &c.

There are two anatomical forms of this affection; the one non-circumscribed, the other circumscribed.

a. Non-circumscribed Gangrene.—This is one of the rarest forms of organic diseases. Laennec saw but two cases in twenty-four years. You have before you, gentlemen, a beautiful preparation of the lung in this state.

The pulmonary structure is more humid, and easier to tear, than in the natural state; it is of the same density as in peripneumonic or cadaveric, or serous engorgements of its tissue. Its colour varies from shades of dirty white and slight green to a dark or almost blackish green, sometimes combined with a mixture of brown or dirty yellowish brown: these various tints are often irregularly mixed. The lungs also, around the gangrenous part, is infiltrated

with sanguineous serum, and is, in fact, in a state of peripneumonic engorgement; the gangrenous part falls into a state of putrid deliquium. You perceive that a large portion of this lung hangs in filaments. A sanious fluid, of a greenish-black tint, oftentimes mixed with blood, and possessing a most horrible fœtor, flows from the diseased mass.

The non-circumscribed gangrene occupies always the largest portion of a lobe, and frequently a whole lung. In some points the healthy pulmonary structure confounds itself insensibly with the gangrenous parts; in others, the lung is in a state of peripneumonic engorgement around the disease: rarely, and only in a few points, is it hepatized.

b. Circumscribed gangrene.—This species differs from the preceding, by its occupying only a small part of a lung; by its slight tendency to invade the surrounding parts; and by its being a more chronic affection.

Circumscribed gangrene may be considered in relation to three states—1st, gangrenous eschar; 2d, deliquescent sphacelus; 3d, excavation resulting from the evacuation of the gangrenous matter.

1. *Gangrenous eschar.*—A gangrenous eschar is irregular in its form and size; its colour is greenish-black; its texture more humid, compact, and hard, than that of the healthy lung. It presents the appearance of an eschar formed upon the skin by the action of lunar caustic, and has a distinct gangrenous odour. The surrounding lung, to a certain extent, is in a state of engorgement or hepatization.

2. *Deliquescent sphacelus.*—The eschar gradually becomes blacker, or brown, or yellow; it softens into a filamentous mass, and remains sunk in a depression, formed by the destruction of the surrounding mortified parts.

More commonly the eschar softens into a kind of putrid “bouillie,” of a dirty green colour, sanguinous, and horribly fetid. This matter bursts into the nearest bronchial tubes, is gradually evacuated, and leaves an ulcerous excavation.

3. *Gangrenous excavation.*—The pulmonary tissue surrounding the excavation is infiltrated with a dark-coloured fetid serosity; after several days, points of hepatization appear disseminated upon its surface. The colour of the engorged lung is reddish black, and the organ where diseased contains but very little air.

When the eschar separates, the parietes of the cavity become lined with a false membrane of a grey or dirty yellow colour. This membrane is opaque, soft, and secretes a turbid pus, or black sanies, of a gangrenous smell. Sometimes the false membrane is produced even before the separation of the eschar, forming a line of

demarcation between the dead and living parts.

Often the pseudo-membrane does not exist; and then the fetid pus is secreted from the parietes of the ulcer itself. These parietes are then firm, creak when cut with a scalpel, and are of a certain dryness. If incised, the surface is seen granular. This state of the lung rarely extends more than half an inch or an inch from the excavation, although it has been seen to occupy the whole lobe in which the cavity is situated. In other cases the parietes are soft, as if fungoid and putrid: large blood-vessels are occasionally seen traversing the cavity, denuded and isolated, but intact; at other times these vessels are partially destroyed, and their open mouths give occasion to a hæmorrhagy, which fills the excavation with clots of blood, and may produce a fatal hæmoptysis.

The decomposed gangrenous eschar occasionally opens into the plenra, and causes pleuritis, accompanied by pneumo-thorax: not unfrequently, a series of gangrenous excavations exist, more or less communicating with each other, and often establishing a direct passage for the air from the trachea into the pleuritic cavity.

State of the Bronchi in Peripneumonia.—The mucous membrane of the bronchi is usually highly reddened in peripneumonia, although rarely swollen: when purulent infiltration supervenes, it is rendered sometimes pale, or of a more intense and violet red; and its tissue softens.

Situation of Peripneumonia.—Peripneumonia almost always commences at the lower lobes of the lungs, and has a strong tendency to invade the different portions of the organ from below upwards: of course the succession of morbid changes will therefore occur soonest in the inferior lobes; so that supposing a whole lung to be inflamed, and a perpendicular section to be made of it, from its apex to its base, the lower part will be found in a state of purulent infiltration, the middle in that of hepatization, and the superior engorged with bloody serum. You must always observe, however, that the lines of demarcation of these states are rarely perfectly marked and distinct, but that they run into each other by an insensible mixture or gradation.

Anatomical Characters of the Resolution of Peripneumonia: Engorgement.—The red serous fluid infiltrated into the tissue of the lung is absorbed, and the pulmonary structure becomes as dry as usual; a colourless serosity, however, frequently succeeds to the bloody serum, and remains for an uncertain time.

Hepatization.—The hardened parts first become pale, and pass from a red state to

a grey or violet, and then to the natural colour; but they frequently remain somewhat redder after they become permeable to the air. While these changes of colour succeed each other, the lung loses its hardness, becomes more humid, and appears to contain more serosity than blood; which serosity becomes gradually more and more spumous.

The granular aspect of the hepatized lung gives way to the reappearance of the aerian vesicles. The diseased parts remain for some time more firm, elastic, and heavier than natural, no doubt from the hypertrophy of the parietes of the air cells. The resolution does not proceed equally, for some points may be seen here and there hepatized in their centres, whilst their circumference is confounded by an insensible gradation of the inflammatory engorgement into the healthy structure.

Purulent infiltration.—When the disease has arrived even at this stage, Laennec affirms that resolution may take place without any disorganization of the pulmonary substance. At the commencement of the resolution the yellow colour of the lung becomes paler and whiter; the pus is mixed with serosity, which contains a little air; the pus gradually diminishes, and puts on a grumous appearance; the air cells become again apparent; the lung now feels firmer than in peripneumonic or serous engorgement, and it crepitates slightly under the finger. The surface of a section is of a very pale dirty yellow, or green. If the resolution is very advanced, this tint alone remains, and the pulmonary tissue is only slightly infiltrated with serosity, which finally is absorbed.

Duration of the different stages of peripneumonia.—This disease is highly acute in its nature, rapid in its course, and requires the prompt use of remedial means; its duration is nevertheless variable. Laennec has seen the state of engorgement last seven or eight days, and invading the whole of one lung, and part of another, before any portion was hepatized. This was the case in the influenza of 1803 and 4, and I had repeated occasions to see the same in that of last year. In other instances, and particularly in weak and aged persons, or when combined with any other serious malady, the inflammation passes into the state of purulent infiltration in thirty-six, or even twenty-four hours.

Usually the disease runs the following course: the engorgement lasts from twelve hours to three days before the hepatization is complete; the hepatization lasts three days before points of purulent infiltration shew themselves; and from that time until the pus is softened, it varies from two to six days.

This duration of the different stages of peripneumonia must be greatly changed by the mode of treatment, and the first and second stage thereby greatly prolonged. Thus I have seen several instances of the lung remaining hepatized for many weeks.

This, gentlemen, is the description given by Laennec, of the various anatomical conditions of the lung in peripneumonia and gangrene of that organ. It is so perfectly accurate, that I have thought it right to give it almost in his very words.

[A series of preparations and drawings, illustrative of every stage of the disease, were exhibited during the lecture.]

THE ANATOMY AND PHYSIOLOGY OF THE LIVER.

By FRANCIS KIERNAN, ESQ.

Member of the Royal College of Surgeons, late Teacher of Anatomy.

[Condensed from the Philosophical Transactions.*]

THE following pages contain an account of my own investigations of the structure of this organ. The description I propose to give will embrace, 1st, that of the lobules, the manner of their arrangement, their connexions with each other and with the vessels; 2dly, the surfaces of the liver and the distribution of the vessels; and 3dly, the structure of the lobules.

Of the Lobules.—The hepatic veins with the lobules present a tolerably accurate resemblance to the trunk, branches, and leaves of a tree (fig. 1, page 332.) The lobules may be compared to the leaves. The substance of the lobules is arranged around the minute branches of the veins in a manner which may be compared to the disposition of the parenchyma of a leaf around its fibres. The vessels in which the minute veins terminate may be compared to the branches of the tree, and these vessels, by their junction, form the trunks. The hepatic veins may be divided into two classes; into those veins contained in the lobules, and those contained in canals formed by the lobules. The first class is composed of the interlobular branches, one of which occupies the centre of each lobule, and receives the blood from a plexus formed in the lobule of the portal vein. The second class of hepatic veins is composed of all those vessels contained in canals formed by the lobules. Numerous small branches, as well as the large trunks which terminate

* Our condensation of this very elaborate and valuable paper, consists in the omission of certain passages, chiefly containing the opinions of others; but not a word of what we have given is altered from the text of the author.—ED. GAZ.

in the inferior cava, are included in this class; they all resemble each other in being contained in canals, and they differ from the vessels of the first class, which are contained in the lobules. The intralobular veins terminate in some of these vessels, and not in others; these vessels therefore admit of being divided into two sets; 1st, those in which the intralobular branches terminate; 2d, those in which no intralobular branches terminate. The lobules are arranged around the veins composing the first set, the bases of these bodies resting upon them: they may be called the sublobular-hepatic veins, this term being applied to them merely to distinguish them from the trunks which compose the second set, and on which the bases of the lobules do not rest. The branches of the second set are formed by the junction of those of the first; the canals containing the former differ in the manner of their formation from those containing the latter. Every branch of the hepatic veins contained in the liver belongs to one of these two classes of vessels.

Each intralobular vein is composed of a central vessel, and of from four to six or eight smaller vessels, which terminate in the central vessel. (Fig. 1, *e*, p. 332.) The intralobular veins invariably correspond in form with the lobules, the substance of which is arranged around them; and as these vessels resemble in some degree the fibres of a leaf, so sections of the lobules made in the direction of the vessels assume a more or less foliated appearance. (Fig. 1, *b*.) The lobules are not, however, flattened bodies like leaves; for, as the smaller veins enter the central vein in every direction, so small processes project in every direction from the lobules, the number of processes being equal to the number of veins terminating in the central vein. The form of the lobules will be now easily understood; their dimensions are known to all anatomists. They are small bodies, arranged in close contact around the sublobular hepatic veins, each presenting two surfaces. One surface of every lobule, which may be called its base, rests upon a sublobular vein, to which it is connected by the intralobular vein running through its centre, the base of the lobule thus entering into the formation of the canal in which the sublobular vein is contained. (Fig. 1, *c*.) The canals containing the hepatic veins may be called the hepatic-venous canals or surfaces; and as the base of every lobule rests on a sublobular vein, it is evident that the canals containing these veins are formed by the bases of all the lobules of the liver. The external or capsular surface of every lobule (fig. 1, *d*.) is covered by an expansion of Glisson's capsule, by which it is connected

to, and separated from, the contiguous lobules, and in which branches of the hepatic duct, portal vein, and hepatic artery, ramify. All the lobules resemble each other in their general form, and they are all of nearly equal dimensions; they appear larger when the section is made in the direction of the hepatic veins, and smaller when in the transverse direction. This is most apparent in that state of the liver usually called the nutmeg liver. In a longitudinal section of a lobule, the intralobular vein is seen running through its centre; and if on the surface of the section five of the projecting processes of the lobule be seen, five smaller veins will also be seen, one occupying the centre of each process, and all terminating in the central vein. (Fig. 1, *f*, p. 332.) In a transverse section of a lobule, the divided extremity of the interlobular vein is seen in the centre, and three or four processes of the lobule are seen shooting out in different directions. (Fig. 2, *b*.) The vein being thus always situated in the centre, it sometimes happens that on the surface of a section of the liver, veins are seen in some lobules and not in others: this appearance is caused by the instrument, which, passing obliquely through these lobules, divides some vessels, which thus become apparent, and passes either above or below others.

The superficial differ in one respect from the internal lobules. In the latter, the intralobular veins commence at a certain distance from the surfaces of these bodies, the substance of which completely surrounds them, except at the bases of the lobules, where the veins make their exit to terminate in the sublobular veins. By superficial lobules are meant, not those only which form the convex and concave surfaces, but those also the capsular surfaces of which form the canals containing certain branches of the hepatic duct, portal vein, and hepatic artery, and the canals containing the trunks of the hepatic veins, all these canals being tubular inflections inwards of the superficies of the liver. In all the superficial lobules, the intralobular veins commence immediately at the surfaces; these lobules appearing less perfect in form, or less developed, than those of the interior, or as if their upper portions had been removed, giving to the surfaces of the organ the appearance of the surface of a section. The knowledge of this peculiar form of the superficial lobules enables us, in injecting the hepatic veins, to limit the injection to this system of vessels, which is effected by withdrawing the syringe when the injection appears in minute points on the surface of the liver. If the injection be propelled from the hepatic veins into those portions of the lobular venous plexuses immediately surrounding

the intralobular veins, the first stage of hepatic venous congestion will be simulated: this is effected by withdrawing the syringe when the injection appears in small isolated patches on the surface. The next stage of congestion will be simulated by propelling the injection until the patches partially coalesce, and become continuous with each other; and finally, the appearance of general congestion is produced when the injection passes into those branches of the portal vein which ramify in the interlobular fissures. Occasionally double lobules, or lobules having two intralobular veins, are observed on the surface.

Mascagni, adopting Malpighi's view of the arrangement of the lobules, compares the liver to a bunch of grapes; and this anatomist and Bidloo have represented the lobules appended to the extremities of the vena portæ. As certain branches of this vein first ramify between the lobules, and finally enter them, these bodies may be represented as appended to its extremities; and although every lobule receives branches from this vein, yet a certain number only are clustered around its trunks, with which they have no immediate connexion; whereas the base of every lobule in the liver is in contact with, and connected to, an hepatic vein.

The essential part of a gland is undoubtedly its duct; vessels it possesses in common with every other organ; and it may be thought that in the above description too much importance is attached to the hepatic veins: but relations similar to those which exist between these veins and the lobules, do not exist between the latter and the ducts, or between them and any other set of vessels; nor is there the same exact relation between the ducts and lobules as between these bodies and the hepatic veins; for a lobule with six projecting processes may have three times that number of ducts ramifying on its external surface, whereas the same lobule will have but six minute veins, one in each process, all of which terminate in the central intralobular vein.

Of the Surfaces of the Liver.—The surfaces of the liver are, 1st, the external surface; 2dly, the portal surfaces or canals, at which the vessels enter the organ; 3dly, the hepatic-venous surfaces or canals, at which the vessels make their exit.

Of the external surface.—Examined on the external surface of the liver, the lobules present every variety of form; but in one subject they may all be more or less angular, and in another rounded. They are separated from each other by fissures, which, at the angles of the lobules, dilate into small triangular spaces; they may be called the interlobular fissures and spaces;

they contain the interlobular branches of the portal vein, hepatic artery, and hepatic duct, ramifying in a fine cellular tissue continuous with Glisson's capsule, which, with the vessels, constitutes the capsules of the lobules. (Fig. 3, *b* and *c*, p. 332.) When there is but little cellular tissue in the capsules, the lobules are closely compacted together; they are therefore angular in form, and the fissures and spaces are less apparent. (Fig. 3.) Hence it is that these bodies have been described as having six or more sides by Malpighi, Soemmerring, and others. But when the cellular tissue composing the capsules is more abundant, the fissures, and particularly the spaces containing it, are wider and more apparent; the lobules are less closely connected, they touch each other by two or three points only, and consequently approach more or less to the circular or oval form. Hence they have been described as, and present very much the appearance of, convolutions and undulating bands. They are generally angular where they are most numerous, as in the thickest part of the liver; in these parts also they appear smaller, for being arranged vertically to the surface, their extremities alone are seen. At the edges of the liver, where they are fewer in number, and less closely connected, they are rounded; and lying in an oblique or parallel direction to the surface, they appear larger. They are more angular in children than in adults; in some animals, as in the cat, they are always more angular than in others, as in the rabbit, hare, and sheep; their angular or rounded form always depending on the quantity of cellular tissue composing Glisson's capsule. They appear smaller, are more equal in size, and regular in form, on the convex than on the concave surface of the liver, where they are arranged obliquely, the hepatic veins for the most part running nearer to this surface. An intralobular hepatic vein occupies the centre of each superficial lobule. If the extremity alone of a lobule reach the surface, a more point will be seen in its centre; if a greater portion of the lobule be seen, two or three dark lines will be observed uniting together at a dark point; this point is the central intralobular vein, in which the smaller veins terminate. (Fig. 3, *d* and *e*.) Frequently, lobules with eight or ten projecting processes are found on the surface, each process sending a vein to the intralobular vein running through the centre. It is evident that these superficial lobules are less perfect in form, or less developed, than the internal lobules, in which the veins are wholly surrounded by the substance; and that a superficial lobule with eight or ten processes, is, accurately speaking, half a lobule lying paral-

led to the surface. Lobules lying parallel to the surface may be always seen on the under and posterior part of the left lobe; such lobules are larger and more numerous in the liver of the sheep, rabbit, hare, and squirrel, than in the human liver. A striking difference will be observed if, in the liver of the sheep, these parallel lobules on the posterior part of the concave surface be contrasted with those forming the lobulus Spigelii. The difference between the superficial and internal lobules is satisfactorily proved by injections. If the hepatic veins be injected with blue size, and the portal vein with red, the blue will be found on the surface of every section, in the centres of the lobules, separated by the substance of these bodies from the portal veins occupying the interlobular fissures. If these lobules were, like those of the surfaces, perforated from one extremity to the other by the intralobular veins, the blue and red injection, or the intralobular hepatic veins and the interlobular portal veins, would, in some places at least, be seen in contact, which is never the case.

The veins and fissures cannot be always seen without the aid of a magnifying glass; slight pressure, however, by which the blood is propelled into them, will generally make them visible. They may be always seen after a few hours maceration in water, or they may be shown by mercurial or size injections. For this purpose a liver containing the smallest quantity of blood should be chosen; and on this account the liver of the sheep is preferable to the human liver, the latter being generally in a state of congestion. The vena cava should be opened at its posterior part, and the mercury should be poured from a quill into the hepatic vein of the lobulus Spigelii. With slight pressure the mercury will appear in the centres of the lobules, in the form of lines, stellæ, or points, surrounded by what has been called the red substance of the liver. If the liver contain much blood, the experiment may not succeed, for the blood will be propelled to the surface, and the vessels within the lobules will be no longer distinguishable from those between them. If the pressure be discontinued, the elasticity of the vessels will cause the mercury to retreat from the surface; if the pressure be renewed and slightly increased, the mercury will pass from the intralobular branches of the hepatic vein into the interlobular branches of the hepatic vein, and will be seen in the centre and at the circumference of every lobule. If the mercury be thrown into a branch of the portal vein, it will appear in the interlobular branches situated in the fissures and spaces. In the portal veins, which ramify in the cellulæ-vascular cap-

sules of the lobules, the mercury will have a dull appearance; it will be of its usual brilliancy in the intralobular veins, which, contained within the lobules, have no cellular tissue surrounding them.

Of the portal canals.—These canals commence at the transverse fissure, where they are continuous with the concave surface of the liver; they contain the hepatic ducts, the portal veins, the hepatic arteries, and the vaginal branches of all these vessels, with the nerves and absorbents, enveloped in a sheath of cellular tissue, first described by Glisson, and called Glisson's capsule. If a longitudinal section of one of these canals be made, and the contents be dissected out, lobules, spaces, and fissures, will be seen, arranged in a precisely similar manner to those already described on the external surface. The lobules forming the parietes of the canals are similar to those of the surface, being, like them, perforated by the intralobular veins; they may be called the portal canals or surfaces, the portal vein being the largest vessel contained in them. These canals, and those containing the large hepatic trunks, are formed by the capsular surfaces of a limited number of lobules; the canals containing the sublobular-hepatic veins are formed by the bases of all the lobules.

Glisson's capsule is not mere cellular tissue; it is to the liver what the pia mater is to the brain; it is a cellulæ-vascular membrane, in which the vessels divide and subdivide to an extreme degree of minuteness; which lines the portal canals, forming sheaths for the larger vessels contained in them, and a web in which the smaller vessels ramify; which enters the interlobular fissures, and, with the vessels, forms the capsules of the lobules; and which finally enters the lobules, and, with the blood-vessels, expands itself over the secreting biliary ducts. Hence arises a natural division of the capsule into three portions, a vaginal, an interlobular, and a lobular portion; and as the vessels ramify in the capsule, their branches admit of a similar division.

At the transverse fissure, the duct, vein, and artery, divide into branches, which enter the portal canals. These branches divide and subdivide into smaller branches, which enter smaller canals, and every canal, however small, contains one principal branch of each of these vessels; frequently, however, two ducts and two arteries are contained in the same canal. To these larger vessels the terms of hepatic ducts, portal veins, and hepatic arteries, may be confined, in order to distinguish them from the branches.

The excreting ducts are composed of the hepatic ducts, contained in the canals, of their vaginal branches, also contained in

the canals, and of the interlobular branches, which, arising from the vaginal branches, ramify in the interlobular fissures. The interlobular ducts enter the lobules, in which they form plexuses. These plexuses may be called the lobular biliary, or secreting biliary plexuses, the ducts composing them being the secreting organs of the bile. The excreting ducts and their branches are invariably accompanied by the arteries and portal veins and their branches, the former conveying blood to their coats, the latter conveying it from them: a duct is never unaccompanied by an artery and vein, the vein being always a branch of the portal vein. The veins and arteries also enter the lobules. The veins form plexuses, the branches of which terminate in the intralobular hepatic veins; from the blood circulating through the plexuses, the bile is secreted. The lobular arteries are exceedingly minute, and few in number; they are the nutrient vessels of the lobules, and probably terminate in the plexuses formed by the portal vein. From the ducts, veins, and arteries, therefore, three sets of branches arise, namely, the vaginal, the interlobular, and the lobular branches.

Of the Vaginal Portion of Glisson's Capsule, and of its Vessels—A branch of each vessel, contained in a portal canal, makes its exit from the canal at each interlobular space on its surface. The lobules being small bodies, the interlobular spaces are necessarily numerous, and close together. The hepatic duct and artery running together on one side of the canal, or winding spirally within it, are in apposition with but a very limited number of spaces; the two vessels are, however, brought into apposition with all the spaces by means of plexuses, from which the interlobular branches arise. The portal vein also forms a plexus, being separated from the spaces by the duct and artery and their plexuses. The branches forming these plexuses are the first which arise from the duct, artery, and vein; they form a vascular sheath around these vessels, and may be called their vaginal branches; they ramify in a loose and fine cellular tissue, which, with them, constitutes the vaginal portion of Glisson's capsule. This cellular tissue is continuous with that surrounding the vessels in the right edge of the lesser omentum, and with that of the proper capsule of Laennec. The internal surface of the cellulo-vascular sheath is in contact with the three principal vessels, and is composed of the largest branches arising from them. Its external surface is in contact with the pareties of the canal, and is composed of the smallest branches; these branches form a reticulated plexus, from which the interlobular branches shoot

out, and entering every interlobular space, ramify between the lobules. In the smaller canals, the fissures and spaces being less numerous, and the plexuses formed by the duct and artery being consequently less complicated, a great portion of the portal vein is in contact with the pareties of the canal. In these canals many of the interlobular veins arise immediately from the trunks, vaginal branches being given off, and forming a plexus, on that side only of the canal occupied by the duct and artery. In these canals we find the capsule, the essential part of which is the plexus, only on that side which is occupied by the duct and artery, the vein being in contact on the opposite side with the pareties of the canal. In the larger canals, in which the lobules and spaces are more numerous, and the plexuses necessarily more complicated, the sheath completely surrounds the three vessels. These two modes of arrangement of the capsule may be ascertained by making transverse sections of canals of different calibre. In a small canal in which the capsule is found only on that side occupied by the duct and artery, the portal vein should be laid open, and its internal surface examined. The fissures and lobules will be seen through the transparent coats of the vein on that side on which there is no capsule, and on the internal surface of the vein numerous minute orifices will be observed, corresponding exactly to the interlobular spaces. These orifices are the mouths of interlobular veins, which enter the spaces without contributing to the formation of the plexus. (Fig. 4, *b*, p. 332.) A few larger orifices, not corresponding to the spaces, will also be seen: these are the mouths of the vaginal branches, which divide in the canal into two, three, or more interlobular branches, and thus contribute partially to form the plexus. On that side of the vein which is in contact with the artery and duct, and separated by them from the spaces, the orifices are larger and less numerous; these are the mouths of vaginal branches, which, ramifying in the canal, terminate in interlobular branches, which enter those spaces covered by the duct and artery. (Fig. 4, *c*.)

From the above description it is evident that Glisson's capsule is a cellulo-vascular membrane, composed of the vaginal branches of the duct, vein, and artery, ramifying in a layer of cellular tissue. Its existence around the three vessels in the larger canals, in which the vaginal plexus is most complicated; its existence on that side only of the smaller canals occupied by the duct and artery, and its almost total absence on the opposite side, sufficiently prove that by its means the

three vessels are brought into apposition with all the interlobular spaces on the surfaces of the canals. The vaginal vessels are best seen by making longitudinal sections of canals, and dissecting out the three large vessels after having injected them. The mouths of the interlobular branches arising from the smaller portal veins may be shown by opening a vessel, and removing the injection carefully from the trunk, leaving it in the branches. The internal surfaces of the ducts and arteries exhibit no orifices of interlobular branches, these branches always arising from the plexus which each duct and artery, however small, forms in the canal in which it is contained. The portal vein, like other vessels, occasionally varies in the manner in which it gives off its branches; thus, even in the smallest canals, it frequently happens that the three vessels are surrounded by the capsule. In this case the vein gives off vaginal branches only, and no interlobular branches, all the latter arising from the former.

The first vaginal branches of the ducts arise at nearly right angles with the trunks; they run in a transverse direction within the inner surface of the canal, and terminate in branches which correspond to, and lie on, the fissures. Each transverse branch gives off one or two branches which ramify in the direction of the trunk, and one or two recurrent branches. All these branches run in the direction of the fissures, forming angles at the spaces over which they pass. At each angle a smaller branch is given off, which runs on a fissure leading from the space over which the angle in the vessel is formed. Thus, if the vessels be well injected, all the fissures and spaces will be covered by small ducts, which form a network of vessels corresponding in form to the fissures on which they lie. The transverse branches, and those which arise immediately from them, do not anastomose with each other, but the smaller branches sometimes appear to do so; I cannot, however, from dissection, affirm that they do, for those which appear to anastomose are exceedingly small vessels, and meet each other at the spaces; hence it is difficult to ascertain whether they really anastomose, or enter the space together without anastomosing. From the vaginal ducts spread over the surface of the canal, lobular and interlobular ducts arise; the former enter the lobules on the parietes of the canals; the latter leave the canals at the spaces to ramify between the lobules, which they finally enter. The vaginal ducts are sometimes very tortuous in their course.

The coats of the ducts are highly vascular; the rugæ on their internal surface,

and those on the internal surface of the gall bladder, are formed by the ramifications of the larger blood vessels, arteries as well as veins, covered by the mucous membrane. This membrane is studded with vascular papillæ, which become remarkably developed in the diseased ducts so frequently found in sheep and oxen. The smaller ducts are furnished with papillæ only, and to the rupture of the delicate vessels forming these papillæ is to be attributed the facility with which Soemmerring and other anatomists injected the ducts from the arteries and veins, and not to any direct communication between the vessels and the ducts. The ducts cannot be injected in a direct manner from the hepatic vein, no branches of this vein ramifying in their coats; fluid may indeed be made to pass from this vein into the ducts, but only through the medium of those branches of the portal vein which ramify in the coats of the ducts. The ducts are injected from the portal vein and from the hepatic artery in the same manner as the fetal intestine is frequently filled with injection from the umbilical vein or aorta, viz. by the rupture of the minute vessels of the mucous membrane. Hence it is evident that the ducts, so far as they have been yet traced, are abundantly supplied with arterial blood; that this blood returns into the branches of the portal, and not into those of the hepatic veins; and that the hepatic portal vein has branches of origin in the coats of the excreting ducts from the terminations of the hepatic artery, as the abdominal portal vein arises in the coats of the intestines, in the spleen and pancreas, from the arteries of these organs.

From their extreme vascularity alone, we might infer that the ducts serve another purpose beside that of conveyance of bile; and all anatomists are acquainted with the muciparous follicles of the lining membrane of their larger branches: in the smaller branches, the existence of the follicles has been denied. In the former, they are irregularly distributed over the surface; in the latter, they are closely arranged in two longitudinal lines, occupying opposite sides of the ducts; and, arranged in this manner, they will be found in the smallest duct that can be examined. Mappes confounded the follicles with the orifices of vessels. Their number renders it probable that the fluid furnished by them serves another purpose beside that of lubricating the surfaces of the ducts. Some estimate of the quantity of this fluid may be formed by examining the ducts, after having injected them with alcohol. These follicles are probably the secreting organs of all the mucus found in the bile.

The vaginal ducts are accompanied by the vaginal arteries; the latter, however, are more or less tortuous in their course, the former generally proceeding in the shortest direction to their destination. The vaginal arteries anastomose freely with each other, but their ramifications do not, like those of the ducts, correspond exactly to the fissures. If the left artery be injected in the transverse fissure, the injection will return by the right artery: this communication takes place by means of vaginal branches which the left artery gives off in the fissure, and which anastomose with similar branches of the right artery.

The vaginal branches of the vein anastomose with each other; they form a much more complicated plexus in the human liver than in the liver of most animals, and on this account the cellular tissue of Glisson's capsule is more abundant in the former, and greater difficulty is experienced in examining the plexuses formed by the ducts and arteries. In the sheep, portal veins of considerable size resemble the smaller portal veins in the human subject, vaginal branches arising from them on that side only of the canal occupied by the duct and artery, and interlobular branches on the other side. On this side, therefore, we find the cellular tissue in small quantity, no venous plexus being formed, and the injected vaginal ducts and arteries may be seen without dissection through the transparent coats of the vein.

The nerves and deep-seated absorbents ramify in the portal canals; I have not been able to trace them into the interlobular fissures. The absorbents may be always injected from the duct, and the bile is frequently propelled into the former vessels by injecting the latter. Mascagni found that injection thrown into the ducts returned colourless by the absorbents. I have frequently made the same observation, but I have as frequently found the injection in the absorbents of the same colour as that thrown into the duct, and have frequently filled all the absorbents of the right edge of the lesser omentum with red size from the duct. No absorbents accompany the hepatic veins, and it is not probable that any of the absorbents of the liver terminate in the branches of the portal vein, the fluids in these two systems of vessels proceeding in different directions. The superficial absorbents ramify in the proper capsule. After injecting these vessels, the peritoneal coat may be removed without injuring them; or the peritoneal coat may be first removed, and the absorbents afterwards injected; and some few may be injected in the proper capsule after the separate removal of both. This can be done in the human subject and in

the larger animals only, the proper capsule being of a much more delicate structure, or probably not existing, in the smaller animals, in which the liver appears to have no superficial absorbents. Injection sometimes passes from the arteries and portal veins into the absorbents.

Of the Interlobular Portion of Glisson's Capsule, and of its Vessels.—As the interlobular ducts, veins, and arteries, arise from the vaginal ducts, veins and arteries, so the interlobular cellular tissue is continuous with the vaginal cellular tissue, the vessels and cellular tissue together constituting the interlobular portion of Glisson's capsule, which occupies the fissures, and forms the capsules of the lobules. The interlobular vessels, at their origin from the vaginal vessels, enter the spaces; in the spaces, therefore, we find the largest branches; these divide into smaller branches, which ramify in the fissures.

If the left hepatic duct be injected with size or mercury, the injection will return by the right duct, without extravasation and without passing into other vessels, and the injection will be found in the interlobular and vaginal ducts as well as in the trunks. This communication between the two ducts does not take place, like that which exists between the right and left arteries, through the medium of the vaginal branches of the transverse fissure, the injection being found in interlobular branches arising from the right duct. From this experiment, which I have frequently repeated with the same result, it appears that the right and left duct anastomose with each other through the medium of the interlobular ducts. This experiment does not always succeed, which probably arises from the quantity of bile contained in the ducts.

The interlobular branches of the portal vein cover, with their ramifications, the whole external surfaces of the lobules, with the exception of the bases of these bodies, and of those extremities of the superficial lobules which appear on the surfaces of the liver. The freest communications take place between these vessels; when successfully injected, which can be done with size only, the interlobular fissures in which they are contained, whether examined on the surfaces of the liver, or on the surface of a section, are coloured with the injection. Mercury thrown into a large branch of the portal vein returns by other large branches. This communication takes place through the medium of the interlobular branches, for though the vaginal branches in the same canal anastomose freely with each other, yet those of one canal communicate with those of another through the medium of the interven-

ing interlobular branches alone. The interlobular veins also form communications between the lobular veins of a lobule, and those of the contiguous lobules. Hence it appears, contrary to the assertions of Bichat and Mappes, that the freest anastomoses exist between all the branches of the portal vein, and that the interlobular branches form the medium of communication.

When the portal vein is imperfectly injected, and the venous circles, formed by its interlobular branches around the lobules, are not brought into view, these branches are seen in the spaces, and three or four smaller branches are seen shooting into the fissures communicating with the spaces. These are the stellated vessels of anatomists. When the vessels are well injected, the stellæ are all continuous with each other, and the venous circles are formed; the stellated appearance, therefore, arises from the incomplete injection of the vessels. If the liver do not contain much blood, stellæ may be always produced on its surfaces by pressure.

No anastomoses can be shown to exist between the interlobular arteries, these vessels, even when most successfully injected, appearing like points, lines, and stellæ, in the fissures and spaces. The right artery may be injected from the left in the transverse fissure, and it has been shown that this communication takes place by means of the vaginal branches given off by the two arteries in the fissure; but if the left artery, or a branch of it, be injected at its entrance into its canal, after the vaginal branches of the fissure are given off, the injection will not return by the right artery. From this experiment it would appear that no anastomoses take place between the interlobular arteries; but as the vaginal arteries communicate freely with each other, and as the interlobular ducts also communicate with each other, and as the arteries ramify in the coats of the ducts, we may conclude that the interlobular arteries anastomose.

From the superficial interlobular fissures, small arteries emerge and ramify in the proper capsule on the convex and concave surfaces of the liver, and in the ligaments. These are the capsular arteries. They vary much in number in different subjects, being always most numerous in those in which the capsule is most developed. In those animals in which the liver has a peritoneal coat only, and no proper capsule, no capsular arteries can be shown by injection. In those subjects in which the capsular arteries are numerous, these vessels cover the surfaces of the liver with a beautiful plexus: those of the right lobe anastomose with those of the left, and both

anastomose with branches of the phrenic, internal mammary, and supra-renal arteries; some, leaving the liver, ramify under the peritoneum covering the right kidney; others pass along the ligamentum teres to the umbilicus, and anastomose with the epigastric arteries.

All the capsular arteries, arising from whatever source, ramify in the proper capsule, and they may be all injected from the hepatic artery. I have never seen injected vessels in the peritoneum, but as recent adhesions between the liver and diaphragm may be injected from the hepatic artery, it appears evident that the peritoneal coat of the liver is nourished by this artery. That the proper vessels of the liver anastomose with those which Walter calls the proper vessels of the membrane, is proved by the fact, that recent adhesions between the right lung and the diaphragm may be injected from the hepatic artery, the injection passing from the capsular branches of this vessel into those of the phrenic, and thence into the phrenic arteries themselves. The capsular veins are branches of the portal vein; these vessels communicate freely with branches of the phrenic veins. In some cases of atrophy of the liver, and in cases in which the circulation through the liver has been for some time obstructed, a collateral circulation is established by means of the communications which take place between the capsular branches of the hepatic artery and portal vein, and those of the phrenic artery and vein.

All the *vasa vasorum* of the liver are branches of the hepatic artery and portal vein. Branches of the artery ramify in the coats of the duct, artery, and portal vein; veins arise in the coats of all these vessels, and terminate in branches of the portal veins. In the hepatic-venous canals, and in the fissure of the inferior cava, small arteries issue from the interlobular fissures, and ramify in the coats of the hepatic veins and inferior cava: veins arise in the coats of these vessels, and entering the interlobular fissures, terminate in branches of the portal vein. All the veins arising in the coats of the vessels, and terminating in the portal vein, constitute the hepatic origin of this vein.

The trunks of the duct, vein, and artery, in each canal, terminate in interlobular branches. Vaginal vessels, giving off interlobular vessels, ramify in the transverse fissure, in the fissure of the gall-bladder, and in that containing the obliterated umbilical vein and ductus venosus; these fissures, therefore, must be considered as portions of portal canals.

- Fig. 4. Represents a transverse section of a small portal canal and its vessels. The lobules are in a state of general congestion.
- a. The portal vein, a great portion of which is in apposition with the interlobular spaces on the parietes of the canal.
- b. The interlobular branches arising from the trunk and entering the spaces, with the branches of the duct and artery, without ramifying in the canal. On this side the vein resembles an hepatic vein, in having no vaginal branches.
- c. Two vaginal branches arising from the vein, and dividing into interlobular branches on that side of the canal on which the vein is separated from the spaces by the duct and artery. On this side, the vein, giving off vaginal branches, and being separated from the parietes of the canal by the capsule and vessels, resembles the larger portal veins.
- d. The duct giving off vaginal branches.
- e. The artery giving off vaginal branches.
- f. Three vessels, a duct, vein, and artery, entering each interlobular space on the surface of the canal.

OBSERVATIONS ON THE NATURE AND
ORIGIN OF THE DISEASE

CALLED

PLICA POLONICA.

To the Editor of the Medical Gazette.

SIR,

It is singular that in the present advanced state of medical science, any doubts should exist respecting the nature of a disease which, from its circumscribed influence, has received the name of plica polonica; still, even at the present moment, the medical opinion is divided upon the reality of its existence, as a specific complaint. This discordance of opinion is not confined to strangers, or to those medical men who, not having sojourned long in the country where the disease is endemic, have had but little opportunity of investigating the matter, but the medical men resident in those parts where it is most prevalent, do not seem, as far as I could ascertain it, to have made up their minds upon the subject.

There are three opinions, however, which may be quoted regarding the nature of this affection.

The first, and a very general one, that the said plica is nothing more or less than an aggregation of filth.

The second, a very limited one; that it is a specific contagious disease, produced by a peculiar virus.

The third, and the more probable one, that it is a secondary affection, or a critical excretion from the scalp and roots of the hair, and the natural curative process of a variety of complaints.

Several reasons may be assigned for the discrepancy of opinions which exist upon this subject, and which place it among real or artificial diseases. It is in general confined to the lowest orders of society. Such excite little interest or compassion; and their modes of life, which place them, as regards cleanliness, even below many of the brute creation, have acted as an insuperable barrier to the thorough investigation of this disease upon those spots where it is endemic.

When it attacks, on the contrary, the better classes of society, it is studiously concealed from the world in general, and often from the medical attendant; unless, having resisted all nostrums, it

becomes too aggravated in its character to be trifled with any longer.

The same cause has operated in both cases, to prevent sufficient attention having been paid to it in all its stages. The peasant is too filthy to be attended to; the rich man is too proud to allow himself to be suspected of labouring under the curse of that which is the fitter property of his boor. Hence it is that so little real information is to be gained from the number of authors who have written upon this subject. Each has contented himself with re-stating or criticising some preceeding opinion upon the disease; few have taken the trouble to investigate the truth, by observing simply with their own eyes what lay in their daily path. So we are told of the errors into which Hercules de Saxonnia fell, from his too great belief in supernatural agents.

Davidson, on the other hand, is reproached for his scepticism; Schlegel is too diffuse; Gase too concise in his description; but the authors of these criticisms do not think of telling us what they saw themselves. To unfold a plain unvarnished tale, must be left, I believe, to the Ghost of Hamlet; for no one living seems disposed to do it. We find that not only the real existence of the disease is a matter of contention, but its origin and progress are equally twisted, like itself, from the path of truth, by those who believe in its existence. Its name and numerous synonyms indicate a great difference of opinion as to its origin and effects.

First, as to the opinion of many, that it is only an aggregation of filth.

I have myself known it occur in five opulent families, where any question of uncleanness could not for a moment be agitated; and this is itself sufficient to disprove the validity of this sweeping clause.

Having previously to my visiting Poland read several works upon the subject, and found them abounding in controversy and confusion, I was in hopes that during my residence in the ancient capital of the Piasts, I might gain some clearer evidence upon the matter. Being convinced, from what I have already stated, that uncleanness alone could not account for all that I found to exist, it became nevertheless necessary to ascertain how far this operated as a cause, knowing that cause

and effect are often so blended together, that it is difficult to separate them.

Here arose a stumbling block at the threshold of inquiry; and it was necessary to refer to popular prejudices, not as a standard of truth, but as a standard of error, from which truth may often be elicited. I found that there was but one opinion held by the people regarding the effects of the disease, how diverse soever their opinions might be as regarded its causes. All agree that the effects of the plica are most salutary to the system; and there are few earthly blessings which are more coveted by the peasant than the formation of a plica in his hair. Two circumstances meriting attention are to be considered, as arising from this opinion—the one, that relief is afforded to the system under certain morbid states by the formation of a plica; the other, as a necessary consequence, that means will be devised to promote its formation. From these two circumstances arise also a very important subject for consideration, viz., that the methods frequently resorted to, in order to promote this effect, have tended to establish the opinion, that the disease is at all times an artificial production. It is said to be good for the ague, for the gout, for sore eyes, for obstinate headaches; and females find it good for a variety of complaints: consequently, as soon as they are afflicted with any of these grievances, they immediately commence forming an artificial plica. Of this I have positive proof in the following instance.

I was requested to see the daughter of a person in very easy circumstances, who was afflicted with sore eyes, and had a defect in her vision. She was about fourteen years old, and was, when I first saw her, lying upon the bed: her hair was twisted and matted together, and the *animals* in such quantities that I could not approach her without feeling disgust. She had a speck upon one cornea, and seemed to be suffering from rheumatic ophthalmia. Upon inquiring why she was confined to her bed, and if she had the plica, her mother replied not as yet, but she was in hopes that it would not be long in coming; for which purpose her daughter was kept as warm as possible. "For the same reason, I suppose, you do not allow her to comb her hair, or keep her head clean?" "Yes," was the reply.

"And what do you expect will be the consequence?" "A plica will form in her hair, and cure all her complaints." "Will her eyes get well as soon as the plica is formed?" I inquired. "No, not immediately; but as the head gets worse, the eyes will by degrees get better, and when once cured, she will never be subject to have sore eyes again." "How long will this plica last?" I inquired. "About three years," was the reply. "And what then?" "The old hair will die away, new hair will shoot out from the scalp, and then we shall cut away the old by degrees, and she will have a fresh head of hair."

All this information was founded upon the experience of the mother, whose son had suffered, some years previously, in the same way, and was cured by the same means.

Some days later, I visited the public hospital. In passing by one of the beds, I observed an old woman, whose head appeared enveloped in the remains of a flannel petticoat. I inquired what ailed her. The interpreter replied, Koltun, the name given to the disease by the people. I was anxious to examine it myself; the attendant replied, that it was not as yet fully formed, but that she was encouraging it all in her power, and so wrapped up her head in flannel. I inquired why she was so anxious to produce a plica. "The old woman is a martyr to rheumatism, and this is an infallible cure for it—the universal remedy," said the young surgeon who interpreted for me. In the meantime she had taken the wrappings off her head, and I found the hair all twisted together, and very *lively*, as I had observed it in the other patient. The plica was much farther advanced in this latter case. The mass of hair upon the crown of the head resembled a dirty bird's-nest; but upon examining the hairs individually, I could perceive no alteration in their structure. Such a plica might evidently be produced at any time, and as easily in Cork as in Cracow. The old woman was much displeased at being obliged to undo her flannel wrapper, from fear of the exposure to the air retarding the progress of the disease.

These two cases sufficiently prove that means are resorted to in order to produce an agglutination and conglomeration of the hair, for the purpose of

relieving the system of some painful affection; and this forms the false or artificial plica. This is considered by many as the only disease; and when so many cases can be traced to this and this alone, it is not singular that with many further investigation is not considered necessary.

The following case, which occurred to a servant girl in the family of Dr. Typaldoes, an amiable Greek physician, then residing in Cracow, illustrates the relief afforded to the system by the spontaneous appearance of a plica, when no artificial means had previously been used to produce it. She had been afflicted for several months with violent pains in the head, which resisted all medical treatment. As the winter approached, the headaches got worse and worse, and during the night were quite insupportable. In the month of January, the thermometer being 22° Reaumur, she left her bed, and went down stairs to get ice to put upon her head. She caught a severe cold by this imprudence, and a fever, with delirium, was the result. The usual means were employed to combat the fever and head affection, but nothing succeeded, till suddenly a plica formed itself upon the scalp; and she gradually got better as the plica increased.

In such a case, the old term *vis medicatrix natura* seems to establish a claim upon our attention.

It is natural to ask if the plica formed in this spontaneous way, differed in appearance from those which I have described, and which were artificial productions. I cannot reply to this from my own ocular evidence, but Dr. Typaldoes informed me that it was a true plica, for that the structure of the hairs was altered; but the patient immediately resorted to the same artificial means of promoting its increase as the others had done to favour its production in their cases: so that even in this case it soon became impossible to unravel truth from falsehood.

I shall explain what is considered to be the difference between the real and false plica as briefly as possible; but I shall first mention a few circumstances, which may puzzle many who uselessly devote their time to read all the different authors who have written upon this malady.

First, as to the various names given to it by different writers.

A good deal is to be learnt from this variety of appellations, most of which express some supposed or real character in the complaint itself; and first, of the popular name of Koltun, which signifies a stake, because the hair stands out like a pole, or stake. This implies no matting of the hair, as a Medusa's head; no interlacing of the hairs in meshes; but a thickening of the hair, either from conjunction of several hairs in a straight direction, or from a thickening of individual hairs; and many have drawn a distinction between the true and false plica, from the disposition of the hairs alone.

When it affects other parts of the body than the head, this is the form which it is said always to assume; and we read of cases where it has increased to such a length as to pass three times round the thigh. The vulgar name koltun is not to be disregarded in the investigation of the nature of this disease.

The following name I shall quote as offering one of the many difficulties which occur in the study of this malady.

Plica judaica, Judenzopf, are commonly met with in writers, and yet I was informed by my colleagues, in Cracow, that the plica was rarely to be met with among the tribes of Israel. If such be the case, it affords negative evidence, at least, to the opinion that this malady is engendered by filth alone; for if there is a mass of living filth in human shape, it is to be found in a Polish Jew, who stalks up and down the streets in a long gown, and fur cap upon his head, nor changes his gabardine till it falls piecemeal off his body, rotted by age. His long flowing hair, falling in ringlets upon his shoulders, and curling at the extremity, would seem to offer a fine nursery for plica: still, as I was informed, he is seldom attacked by this disease, but enjoys, as a substitute more generally diffused over his body, the psoriasis. It was not asserted that no cases are to be found among the Jews of this malady, but that there were but few, comparatively with the peasants. I recollect seeing but one Jew affected with plica, during the time I remained at Cracow.

Another name, and one indicative of its locality, is Weichzelzopf; because it is found to prevail especially on the banks of the Vistula, and the popular tradition runs, that when the Tartar

hordes came over the Carpathian mountains, and invaded Poland, they poisoned the sources of this river.

In the name of Mahrenflechten is expressed that the Moravians, when enemies to Poland, had recourse to magic to conquer them, and gave them this unseemly complaint. So witchcraft is likewise expressed in Hexenzopf.

Thus much for nomenclature; and as to locality, I can only state what I have myself observed. This is, again, a much disputed point; some asserting that it is confined entirely to Poland, others that it is to be found sporadically scattered over Hungary and many parts of the north of Germany. Mr. Russell says "it is found in Livonia and some other parts of Russia, and, above all, in Tartary."

I found it prevalent in the republic of Cracow, in the kingdom of Poland, and in the whole province of Galicia, along the banks of the Vistula. In quitting this river, I lost sight of the disease, nor did I find any traces of it during some weeks' sojourn in the Ukraine and in the province of Podolia, as far down as Odessa.

I have never seen a single case in Russia proper, nor even in Finland; which all coincides with what others have written upon the subject.

Such evidence must go far to prove that filth cannot be the only source of this complaint. Some stray cases may occur in other countries bordering on Poland, but in none that I have mentioned is it a disease of the country.

Another point of controversy is with respect to the disease attacking strangers. Some assert that strangers are not susceptible of it; others, that they only become so when they adopt the costume of the country: both these opinions are erroneous. An instance of the contrary occurred in the family in which I was residing. A lady's maid, who came from Berlin, to attend the Countess —, was very seriously attacked with this complaint: it commenced by headaches and general rheumatic pains, and finally terminated in plica. Now this young woman, from the middle class of society, had not been more than six months in the family, and had adopted no national costume. I know not what may have been the dress of a lady's maid in the time of the Casimirs, but at present, I believe, it is the same over Europe in general.

Neither, therefore, are strangers free from it, nor is it produced by dress alone.

Some have stated that the disease is contagious; but this opinion is combated by one of the earliest writers — viz. Hercules de Saxonia, who published in 1600, and from whose book much is to be learnt. He is quite furious at the idea, and instances, in incontrovertible evidence to the contrary, that a learned professor, of his acquaintance, was afflicted with it to a grievous extent, but his barber, who shaved him and dressed his plica, did not catch the disease. This author does not believe that the plica is ever epidemic, although he has great faith in sol-lunar influence and the aspects of the heavens upon complaints in general. As to its endemic character, he can point out the spots where it is to be found at all seasons of the year.

Mr. Russell has fallen into error upon this subject. He says that "it is contagious, and moreover may become hereditary. In Cracow there is a family, the father of which had the *weichelzopf*, but seemed to be thoroughly cured of it; he married shortly afterwards, and his wife was speedily subjected to the same disorder, and of the three children she bore to him, every one inherited the disease."

Had the author stated that the complaints which engendered plica are hereditary, he would have been nearer the mark; but neither cause nor effect, in this case, can be considered contagious.

With respect to its affecting the brute creation, the opinion is generally in favour of this idea. Pigs and horses are particularly subject to it. Schlegel is of opinion that it is so prevalent among horses, that one out of six is attacked by it, both in Moscow and Petersburg; a privilege which the cattle enjoy over the people in these capitals. Six years' residence in the latter city, and a considerable acquaintance with horse-flesh, have not yet introduced to me the disease in that animal.

In travelling from Cracow to Leopold, I observed that the manes of the peasants' horses had a peculiar appearance, and that the pigs were much in the same predicament. The postilions informed me that it was the *koltun*. Upon close examination, however, I could not convince myself but that a comb would unravel it, if regularly applied. It is too much, however, to expect that

a man should comb his horse who never as yet combed himself.

I shall not dilate more upon the controversies which are to be found in the different works upon this subject: many of the writers are not only at variance with their colleagues, but even with themselves. Few describe what they have themselves seen, or the results of their own study and observation. From what has been said, I think it will be evident that the two first opinions—viz. that the plica is nothing but an aggregation of filth; and, secondly, that it is a contagious disease, depending upon a peculiar virus—are neither of them tenable. The third, or that which allows of its existence, as a critical termination of other complaints, is alone worthy of attention. We do not say, however, that in no instances the hairs may not be affected primarily, but that the disease is not capable of being propagated by contagion, or that the virus can be communicated by inoculation, as many have contended.

G. W. LEFEVRE, M.D.

Physician to the British Embassy.

St. Peter-burgh,
September 1834.

CASES OF SYPHILITIC SORE RESEMBLING CONDYLOMA.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of sending you the reports of two cases, which I hope you will deem worthy of insertion in your widely-circulated journal. Both are the subjects of sores so perfectly resembling simple incipient condylomata, that their nature could not have been detected as differing from them, were it not for their occurring singly, and in situations uncommon for condylomata, and their not disappearing under remedies ordinarily employed for their removal. It would appear as if they originate in the form of a very superficial ulcer, which, though soon cicatrizing, is attended with a diffused but circumscribed induration of the substratum, which, even after the process of cicatrization is effected, increases in depth, (perhaps by increased deposition on their summit, thus becoming more elevated, and at the same time flatter on its surface), but retains the circular form; at least this was the impres-

sion given me by the appearance presented on admission, in the first of the cases here subjoined; and although no appearance of ulceration presented itself in the second case, I attribute this to the circumstance of my not having seen the patient in time to observe the sores in that early stage; and am inclined to consider them as indurated bases of recent sores, though elevated and circumscribed as they were, so resembling the common condylomata. But, without reasoning at all, the history of the cases will not allow us to call them condylomata, as they began with, or immediately followed, the appearance of the gonorrhoeal discharge, the constant and continued irritation of which it is that gives rise to the latter complaint. The true syphilitic nature of this *condylomoid chancre*, if I may so denominate it, is perhaps confirmed by the induration immediately subsiding under the influence of mercury, and not before.

If I be correct in the notion I have expressed, regarding the nature of this affection, it is of the first importance that its existence should be recognized, that no unnecessary delay may occur in the exhibition of that remedy which is necessary for its perfect removal, and to counteract the effects which may result from it; but perhaps the knowledge of such a form of sore is of equal importance in enabling us to reconcile cases which have at times been recorded, of secondary eruptions appearing after condylomata.—I am, sir,

Your obedient servant,

THOMAS PEREGRINE, M.D.

House-Surgeon.

Lock Hospital, Nov. 30, 1834.

CASE I.—Ann Eldridge, æt. 16, admitted September 11, 1834, under Mr. Walker.

Little thick yellow discharge from vagina, with vascularity generally, and here and there tendency to excoriation of its orifice. At the inferior commissure of the vestibulum is a small circular ulcer, with slightly elevated edge, yellowish surface, but bearing a few small red granular points. Left labium slightly swollen; behind its inferior extremity is a circular, hard, and elevated lobular swelling, with scabby surface, presenting the appearance of a *sypilitic sore*, nearly healed, and leaving considerable induration of its base.

Has also bubo in either groin, above Poupart's ligament, large, solid, and painful, but no redness of the skin. Health very good; bowels confined; catamenia regular.

Has had her complaint two weeks. She gives but an imperfect account of it: says that the bubo was the first symptom that she perceived; that the discharge appeared only one week ago; and that the sore in the vestibulum came about the same time; that she has had the swelling of the labium also a week; and the sore behind the lower extremity of the labium she did not notice before to-day.

Has not taken any medicine; she lives temperately, although she has been on the town three months. No previous venereal disease.

II. Sennæ, cras mane; Lotio Saturni, pro lotione, et injectione; Dieta à jusculo.

Sept. 15th (4th day).—

Hyd. Sub. gr. ij.; P. Ant. gr. vj. hæ nocte sd.; II. Sennæ, cras M. sd.; Hirudines, vj. utrique buboni et postea Cataplas. Lini, applique.

17th (6th day).—Buboes smaller, and much less painful.

Lotio Muriatis Ammon. bubonibus; Lotio Nigra ulceri Vestibulo.

28th (9th day).—

Emplastrum Lyttæ buboni sinistro. Rept. H. Sennæ.

25th (14th day).—Discharge diminished; much less vascularity of vestibulum; sore at its inferior part nearly healed. The lobulated induration before noticed on the outside of the lower part of the labium much the same. A similar indurated swelling, or hardened circular tumor, is to-day noticed on the left side of the preputium clitoridis. Buboes dissolving. Has felt ill the last two days; is complaining of pain in the side and in the knees, which are worse at night.

II. Sennæ stat; H. Salin. cum Ant. Tart. 6tis horis.

29th (18th day).—Ulcer in vestibulum healed. Eruption noticed to-day on the thighs, of a tubercular character, with very faint brownish stain. Feels quite well again in health.

Oct. 2d (21st day).—The indurated circular swellings noticed on Sept. 25th, in statu quo.

4th (23d day).—

Pil. Hydrarg. gr. v. bis quotid. Dieta ordinaria.

10th (29th day).—Vaginal discharge decreasing. The induration of the lobular tumors has very much lessened since she has been taking the blue pill; eruption dying away; throat vascular and tender.

Gargarisma Boracis. P. c. Pil. Hydrarg. bis indicies.

16th (35th day).—Improving rapidly; gums vascular and tender.

30th (49th day).—Vaginal discharge stopped for the last two weeks; buboes quite gone; indurated lobule on the outside of the labium disappeared—that on the preputium nearly so; stain of eruption only now remaining; throat well, but disposition to thick secretion. Three soft vascular syphilitic tubercles are seen at the back of the neck, inclined to desquamation: did not notice them before three days ago.

P. c. Pil. Hydrarg. bis indicies.

Made out-patient, at her own request.

CASE II.—Charlotte Godwin, æt. 18, admitted Sept. 18, 1834, under Mr. Briggs.

Irregular excavated ulcer, occupying the inferior part of the vestibulum, inclined to heal; surface yellowish, but studded here and there with incipient red granulations. Margin elevated and rounded; thickening of the surrounding parts. Oedematous swellings of nymphæ, which protrude considerably between the labia; much vascularity of orifice of vagina, with thin yellowish discharge, and slight ardor urinae. *Condylomatous deposits** on the margin of the left labium; health tolerably good; tongue furred; eyes suffused; catamenia regular.

Her complaint began with scalding in micturition two weeks ago; the condylomatous swellings appeared about the same time. The discharge she did not particularly notice till nine days ago; swelling of nymphæ five days. Was not aware of the existence of the sore in the vestibulum.

The previous treatment has not done any thing material.

Is a cook in a private family, so that

* These are the words in my case-book, and entered immediately after the patient's admission, when I was not aware of their nature.

she has always lived regularly. No previous venereal disease.

Haust. Sennæ, cras manâ; Lotio Sat. Dieta c. jusculo.

22d (4th day).—Has a feverish attack; is just recovered from her catamenia, which have been more profuse than ordinary. Sore has become very painful, and assumes somewhat of a greyish aspect, and inclined to spread.

Hyd. Sub. gr. ij.; P. Rhei. gr. vj. stat. sd.; H. Salin. cum Ant. Tart. gr. $\frac{1}{2}$; Mag. Sulph. \mathfrak{g} ij; Tr. Hyoseyami, mxxv. Gtis horis sd.; Lotio Nigra ulceri, cum Cat. Lini.

24th (6th day).—Is very much better to-day. Swelling of nymphæ considerably subsided; ulceration inclined to heal; margin decidedly thickened; much less vascularity of vestibulum.

Beef-tea and pudding.

30th (12th day).—Very much improved; swelling of nymphæ entirely gone; ulcer now quite clean, and granulations sprouting on the surface.

Omit. H. Salin. Magnesie Sulphatis, \mathfrak{g} ij.; Magnesie Carbonatis, \mathfrak{g} j.; Ag. Fontanæ, gr. iss.; Omni mane sd.; P. cum Lotione Nigra ulceri, et Lotione Saturni pro injectione.

October 9th (21st day).—Vaginal discharge stopped three days; ulcer very nearly healed.

14th (26th day).—Ulcer just healed; condylomatous deposits before noticed diminish. d, remaining in the same state as on her admission, though the goulard lotion has been kept constantly applied: they appear precisely similar to the globular induration noticed in the case of Eldridge.

Filulæ Hydrarg. gr. v. bis quotidie. Omit. H. Mag. Sulph. &c. Dieta ordinaria.

29th (41st day).—The two swellings on the labium are softer and more vascular, and a circular yellow ulceration, with a slightly raised and rounded margin, is on their summit*. No sensible mercurial effect on the mouth.

Lotio nigra ulceribus. Pil. Hyd. gr. v. bis die.

November 12th (55th day).—The induration of the lower swelling gone, that of the upper very much less.

P. c. Pil. ter in die.

17th (60th day).—Pil. Hyd. gr. v. Pulv. Opii, gr. $\frac{1}{2}$, ter die.

26th (69th day).—Both lobules now quite gone; there is a little turgescence of the vessels of the gums, and slight pytalism.

27th.—Convalescent. Discharged.

Another patient, lately an inmate in this hospital, was also the subject of a sore, which I have since believed is another example of the form of sore described in the foregoing cases, but of greater magnitude: as, however, it is rather a long case, I will not transcribe it, but extract that portion only which refers to our subject. It occurred in a man (Henry Bachhoffner), art. 22, who was admitted September 11, 1834, under Mr. Walker. Among other complaints, it was mentioned that there was a tubercular deposition above the root of the penis, on the pubes on the right side, covered with a scab; it was painful and indurated. This "tubercle" he had had two weeks. After the scab came off it displayed an ulcerated surface, and the 20th (9th day) the note I made was, that the "tubercle alluded to, above the root of the penis, is a decided syphilitic sore; it is perfectly circular, considerably elevated above the surrounding skin, and now occupied by florid healthy granulations; it has a considerable distinct and circumscribed induration, feeling more like a marble."

29th (18th day).—Sore healing fast, by a white thickened cicatrizing margin; induration subsiding.

October 2d (21st day).—Sore inclined to bleed last two days.

16th (35th day).—Sore healed some days; induration nearly absorbed.

November 1st (51st day).—Thickening of the cicatrix quite gone.

It may be proper to remark that no mercury was administered in this case*, and the common lotio nigra, with the lunar caustic gently applied at intervals, were the only local means employed.

* But he had been pretty liberally mercurialized three several times within the period of six months previous to his admission.

* This is a form of ulceration which the real condyloma never assumes.

CASE OF
COUGH ARISING FROM DIA-
PHRAGMATIC SPASM.

To the Editor of the Medical Gazette.

SIR,

DR. THOMAS DAVIES, in his valuable lectures upon Diseases of the Chest*, speaking of the hysterical cough of females, says, "this disease, as far as my experience extends, attacks young hysterical women. I have met with it thirteen or fourteen times, and never in the other sex." Now, sir, I do not know if the following case can with strict propriety be denominated one of *hysterical* cough, but it certainly is one of an anomalous and somewhat peculiar character—at least it is so to me; and I take the liberty of sending you the hasty outlines of it, that others may, if possible, from my imperfect sketch, form a judgment upon it. As the case only casually presented itself to my notice, and was not under my control, I regret that I did not at the time minutely record the symptoms. It occurred during my residence in a distant part of the country; however, my recollection will enable me to state the more prominent features, as I observed them.

A young man, about 20 years of age, of lax fibre and lymphatic temperament, was seized with a peculiar kind of cough, which recurred at first at rather long intervals, but at the time I saw him it could be produced by the least mental agitation, or a mere effort at volition. It consisted of a series of rapid expirations, in producing which the larynx and glottis appeared almost passive, as the expirations were effected freely, and without the characteristic *hard*, or abrupt sound, attending the alternate contraction and dilatation of the rima glottidis. The upper part of the body, during the paroxysm, was not materially affected, but the disease seemed to be produced solely by the spasmodic contraction of the diaphragmatic and abdominal muscles. During sleep, an intermission occurred. There was no dyspnoea, and no expectoration, indicating disordered functions of the aërian passages. The patient was much harassed by the excessive frequency of the convulsive action, and referred to

the region of the diaphragm as the seat of his malady. The case had encountered a variety of treatment, but nothing had afforded material benefit.

It might be considered almost a solecism to talk of *hysterical* affections occurring in men, did we not know that such affections, or at any rate disorders simulating them, are not of unfrequent occurrence in that sex. In the present instance, had the disease arisen in a female, no reasonable doubt, I conceive, would have been entertained as to its nature. Hiccup alone will sometimes constitute a fit of hysteria; but I am not prepared now to assert that no other just cause can be assigned for the symptoms above detailed.—I am, sir,

Your most obedient servant,

R. H. ALLNATT, M.D.

Wallingford, Dec. 1, 1834.

ON THE
STETHOSCOPIC INDICATIONS
OF PREGNANCY.

To the Editor of the Medical Gazette.

SIR,

SINCE the publication of Dr. Kennedy's "Observations on Obstetric Auscultation," no doubt can be entertained of the value of auscultation, in ascertaining the existence of pregnancy at a period when all visible and tangible signs fail to satisfy the minds of the physician and his anxious applicant. It is a subject of rejoicing to the stethoscopist to witness the utility of his favourite instrument and companion daily increasing, and to see those who formerly affected to despise it now eagerly grasping and consulting it as an unfailing oracle.

Those of your readers who have not been in the habit of using the stethoscope in their midwifery practice, have neglected a means of acquiring much satisfactory information;—for instance, during a tedious labour, the accoucheur is naturally anxious to know the exact state of the child, which may be immediately ascertained by an application of the stethoscope from time to time, instead of trusting to the mother's account of the fetal movements.

The pulsation of the fetal heart varies from 120 to 150; but if the brain be compressed, the number will be much diminished. I had an opportunity of

* See Med. Gaz. Nov. 22, lecture viii.

observing this in a case of protruded funis, that occurred a short time since. When the head had entered the pelvis, during each pain the pulsation of the cord fell from 150 to 90, and immediately on the cessation of the uterine contraction, again bounded away at its usual rate. I merely mention this to guard against error; as, if the compression were long continued, it might be thought that the child were dead, and its pulse of compression be mistaken for the maternal pulse.

In cases requiring embryotomy, it would be a great relief to the operator's mind to possess certain knowledge of the state of the child. I recollect a case in point, in which, after the brain had been extracted, and the body removed, the funis was found to have sloughed and separated at the umbilicus; and I shall not soon forget the expression of delight that illumined the benevolent features of the operator when he beheld that proof of the child's having long ceased to exist. It were useless to enumerate the circumstances in which auscultation might be useful in midwifery practice.

With respect to the placental souffle, its cause has not yet been ascertained. It is synchronous with the maternal pulse, and therefore cannot depend upon the fetus. As there is no vascular communication between the uterus and placenta, it cannot be the result of the maternal heart's action. Is it not, then, possible that it is produced by the rush of blood occasioned by the simultaneous contraction of the returning vessels of the placenta? This idea is not without support. The funis has two pulsatory movements—one of its arteries, and another of its vein, which is felt obscurely beating for a short time after all communication with the child has been cut off. The calibre of the vein is greater than that of the two arteries conjointly, so that more blood may be returned by it than was brought at once by the arteries; and thus a return of blood, as quick as it was brought to the placenta, being rendered unnecessary, is there any reason why the same powers of constitution regulating the beats of the maternal heart should not equally regulate the contraction of the returning vessels of the placenta?—I remain, sir,

Your obedient humble servant,

JOSEPH THOMAS, M.R.C.S.

Wrexham, Nov. 29, 1834.

MEDICAL GAZETTE.

Saturday, December 6, 1834.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

IMPERFECT WORKING OF THE ANATOMY ACT.

It appears quite undeniable that the Anatomy Bill has of late worked very indifferently: in fact, the difficulty of obtaining subjects for dissection never was so great, nor the supply so limited, as it has been during the whole of the present season, and as it still continues to be*. Perhaps not above one student in ten has had the means of studying anatomy practically since the commencement of the courses in October; and the pressure of this evil will be fully understood when it is kept in mind that a considerable proportion of the pupils in the metropolitan schools only come to London for six months, or even for a shorter period, and that they have neither time nor pecuniary means for a longer residence.

This extreme dearth of subjects for dissection, although it has arisen since Mr. Warburton's bill came into operation, cannot fairly be attributed to it, or regarded as at all necessarily flowing from that source. In the winter of 1832-3, the first after the bill had passed, several of the principal schools were well supplied—the teachers, either by means of private interest, or owing to the respectability of the establishments with which they were connected, having been able to induce the directors and guardians of the poor to allow of dissection in cases where no objection had been expressed, agreeably to the provisions of the act. Indeed, the poor themselves,

* As this was passing the press, we learnt that during the last week the supply had again become rather better.—*Ed. Gaz.*

notwithstanding the attempts of a certain portion of the daily press to excite discontent among them, evidently cared very little about the matter; and it was apparent, from the number of bodies thus obtained, that with a little time and management a supply sufficient for the whole of the London schools might reasonably—indeed, confidently—have been expected.

But they who had procured this supply kept it to themselves, alleging, that as there was not yet a sufficient number of subjects for all the schools, those ought first to be provided, the teachers at which had induced the parish authorities to assist them. The result of this was, that at the schools possessing less of this kind of local influence, comparatively few bodies were obtained; and the parties concerned very naturally murmured at the inequality of the distribution. More than one general meeting of anatomical teachers followed; and after some discussion, the expediency of a fair and equal distribution of subjects was concurred in—we believe, by all.

The Inspector of Anatomy was now also requested to give his assistance, as it was thought that some parishes, which were too distant from the schools to be under any influence emanating from them, might yet be induced to contribute towards a general supply, by the solicitation of the Inspector, or by the recommendation of the Secretary for the Home Department. It was proposed that the supplies from the outlying parishes which these official authorities were expected to influence, should be immediately directed into those schools which were most in need of them—with the further provision, that when the number of bodies thus obtained, joined to those already coming in through the channels opened for themselves by particular teachers, should be sufficient for the supply of all the metropolitan

schools, the distribution should then be regulated by one person. The double office of Inspector and Distributor was undertaken by Dr. James Somerville, on the invitation of the anatomical teachers, and certainly with the view of furthering their wishes and objects. That the scheme has proved abortive is in great measure the fault of its own inherent imperfection; but at the same time it may be doubted whether full justice has been done to it;—at least the result has been that very few additional parishes have been procured, while the supply from the others has diminished, since they were required to make over their dead to the Inspector, instead of the parties to oblige whom they were originally given up. After the above arrangement had been made, the anatomical teachers, partly from a wish to avoid interfering with the Inspector, partly from the uncertainty attending the appropriation of any bodies they might procure, and perhaps, also, from other causes, have, during the last year, made no exertion to extend or even to keep up the private supply; and the result has been a most lamentable failure in the necessary means of anatomical study, so that we have complaints before us from almost every school in London.

The subject, indeed, is at present exciting a good deal of notice; and although we have been reluctant to join in the discussion, yet such an opening has now been made, as to render all feelings of delicacy superfluous. At the same time we cannot but regret to observe the vindictive spirit in which the controversy has, in some instances, been conducted. A very bitter article appeared a short time ago in the *Morning Post* (a very absurd paper in which to bring forward such a subject;) and this led to two very coarse letters, by Professor Quain, of the *London University*, through the

appropriate medium of the *Lancet*. The anonymous writer in the *Post* is violent and unjust; his opponent's letters are, perhaps, not quite so abusive, but they astonish no less by their acrimony, than they offend by their extreme vulgarity.

The learned Professor is vehemently opposed to the interference of teachers with parishes, but omits to mention, that he has himself derived the most essential advantage from this source;—he was content while he monopolized the whole of St. Andrew's, Holborn; but it would be too much, perhaps, to have expected equal satisfaction, since, as recently happened, he has been compelled to divide the spoil with others! He accuses those who are dissatisfied with the existing plan, of a desire “to accomplish the destruction of the smaller schools,” though it be notorious that the present system is absolutely ruinous to them, and favourable to him. He asserts, that his opponents would sink the profession of the anatomist “to a state in which it would be adapted only to the taste and habits of a resurrectionist;” and either conceals, or is ignorant of the fact, that the present system has actually recalled these gentry from their abodes of infamy; and that, hearing of the wretched plight of the schools, they have recently made offers to supply them by exhumation!

Not the least remarkable among the many points in Dr. Quain's letters, calculated to excite our special wonder, is the simplicity, or hypocrisy, with which he assumes the continuance of the present plan to be advantageous to the smaller schools, and that any change would be injurious to them. Referring to those who think it would be better to return to the arrangements which, during the first season, procured so much larger a supply of subjects, Dr. Quain says, “But it is notorious that these parties confidently expect that they can accomplish

the destruction of the smaller schools;” and again he tells us of “their long-wished-for object—that of undermining certain schools.” There is no difficulty in discovering from this that the Doctor has a ready pen in imputing bad motives to others; but we confess we have not penetration enough to discover in what manner procuring a better supply of subjects for the smaller schools is calculated to effect their destruction: indeed the glaring discrepancy between notorious facts, and the inferences he has been pleased to draw from them, sometimes leads us to doubt whether the learned Professor be in jest or earnest. Does Dr. Quain mean seriously to imply, that the present system is one satisfactory to the teachers in the “smaller schools?”—that they flourish under it, and desire to see it perpetuated?—that they regard him as their champion, and are grateful to him for his advocacy? We scarcely think he can be so profoundly ignorant of a question on which he has written so elaborately; but if so, we have to inform him, that it is from the private teachers that the complaints have chiefly come—that on them especially has the scarcity of subjects pressed—that they, more than any other class of teachers, are anxious for a change, knowing and feeling that, to them at least, any change must be for the better. But, says Dr. Quain, the present plan allots bodies to the teachers in the ratio of their pupils, and what can be more fair? We answer, first, that this is quite at variance with the affected purpose of befriending the smaller schools; and, secondly, that although nothing can be more fair as regards the distribution of subjects for the dissecting-room, yet nothing can be more unfair if it be applied to the lecture-room. Suppose Mr. A. lectures at a *University* to seventy pupils, and

Mr. B. at a private school to ten; according to Dr. Quain's plan, Mr. A. should have six bodies before Mr. B. got one; and then, there being ten pupils of each unprovided for, both would be equally entitled to one body: A, however, should receive six more before it came to B's turn again! But it is quite clear that as many bodies are required to exhibit the structure of the human frame to the smaller number as to the larger; and therefore, to make the distribution equitable, each teacher who has a license ought to receive a certain supply of bodies, *to enable him to lecture*; while, for the dissecting-room alone, a reference ought to be had to the respective number of pupils.

It is apparent, certainly, that Dr. Quain has heretofore found good reason to be satisfied with the mode of distribution; but that he should represent this as also favourable to the "smaller schools," and himself as standing between them, and "the manœuvres which will be resorted to," we must say, is giving one portion of his brethren among the anatomical teachers credit for as large a share of simplicity, as to others he unhesitatingly assigns of dishonesty and intrigue. Nor is it against those of his own calling alone that the Doctor directs his attack; but with others he deigns to be facetious, and, in playful mood, descends from severer censure to wit and sarcasm. Apostrophizing the patron saint of the *University*, he exclaims—

"Now pray, good Mr. Editor, step with me for a little into the Borough, that we may see how the campaign went on in that quarter. The Borough King won more victories in a few short months than any other potentate whom we know, or have read of. He rode triumphant at every point, carrying all before him. With one hand he smote Grainger, with the other demolished

St. Thomas. By Jove, 'Twas greatly done.'"

It is not in our duller nature to follow up this sportive strain, and therefore, leaving the writer and his companion to "ride triumphant," we return once more to plain facts and common sense. We say, then, that the experience which has been gained by the past, amounts nearly to this:—

1. The poor in workhouses are not disposed to raise any outcry against Mr. Warburton's bill, when its provisions are quietly and decently fulfilled.

2. The directors of the poor, in the parishes adjacent to the schools of most repute, have shewn a willingness to further the objects of the bill.

3. But the parties last-mentioned have made a great (nor do we think either an unnatural or improper) distinction between giving up bodies to schools in their vicinity—to persons whom they know, and of whose proceedings they could have easy observation—and allowing them to be distributed at the choice of a general superintendent, among all the numerous and distant schools of London.

4. The number of bodies supplied by a given parish, depends in a great degree upon the good will of the servants in the workhouse; and so long as the act is *permissive*, not compulsory, it must be so: not, it is pretty evident, that the teachers of a single school in the neighbourhood of any workhouse would more easily and effectually conciliate the important personages alluded to than could be done by a single officer, whose influence and attention are to be divided among all the parishes of the metropolis.

5. The directors of the poor are like any other board. It is not enough that a proposal which is new should be good; it must come recommended by personal interest, and be attended by the

wish to confer personal obligation. The teacher in the neighbouring school makes his application in this manner:—his friend at the board speaks to his colleagues, and a favourable hearing is thus procured for the proposal, what is granted being felt and acknowledged as a voluntary act of patronage and grace. But when the inspector makes his official application, the dignitaries of the parish are arrayed against the interference of the government, and straightway the board discovers it to be cruel and barbarous that the poor should be dissected at the nod of a Minister. Nor is this any imaginary case. At St. Giles's, the directors of the poor intimated that they would give up for dissection the bodies of those dying in their Infirmary, to *certain* schools in their neighbourhood, the teachers of which they thought they could trust for fulfilling the provisions of the act; but added, that if compelled to a general distribution, they would give none. Again: the other day a certain parish intimated that there was a body which might be had for dissection, if sent to St. Bartholomew's. The inspector, in the routine of business, ordered it to be sent to the London University; and the result was that the parish authorities preferred to bury it.

If the preceding observations be correct, the conclusion is inevitable—namely, that the sooner the teachers are allowed to do what they can to aid themselves, the better. A large additional mass of interest will thus be brought to bear upon the parishes, and the supply will no doubt increase—becoming at least as great as it was in 1832-3. It is quite true that this will probably be attended, in the first instance, with some inequality of supply; still there will be bodies somewhere, and the means of studying anatomy will re-exist in London. But though those who happen to have most parish interest

will be best off at first, yet will others be better provided than at present, (worse they cannot be); because they would be relieved from their most absorbing competitors, and the inspector might be able to supply them from the prisons, hulks, and other establishments under government control, as well as by gaining over the outlying parishes to which his exertions would then be limited.

We cannot conclude without adding that Dr. James Somerville has a most difficult and invidious task imposed upon him: he ought not to be required to act both as inspector and distributor; we have heard it likened to combining the offices of receiver and auditor in other things. The impression pervading almost all the accounts sent to us, is, that he has favoured the London University; but no proof of any kind is offered of this, and probably it has originated entirely in his having employed a pupil of that school as his clerk, and in the circumstance of Dr. Quain being almost the only person contented with the present arrangements. It is our sincere belief that the inspector has done all that he possibly could to procure an adequate supply of subjects, and to satisfy the demands of all; but that, under the present circumstances, neither he nor any other individual can accomplish this.

We are glad to find that the College of Surgeons have taken up the matter—having addressed a circular letter to the teachers; and we have little doubt but that we shall soon have to announce some arrangements more satisfactory than the present, the inadequacy of which seem now to be so strongly and generally felt.

The letter alluded to will be found on the other side.

COLLEGE OF SURGEONS.

M. DUPUYTREN'S MUNIFICENT DONATION.

CIRCULAR ADDRESSED TO TEACHERS OF ANATOMY.

It having been represented to the Court of Examiners of the Royal College of Surgeons in London, that the anatomical schools in the metropolis have been very inadequately supplied with subjects for dissection since the commencement of the anatomical session in October last, I shall feel obliged (for the information of the Court), if you will have the goodness to inform me whether this report is true; and if you have reason to complain of great difficulty in teaching anatomy under existing circumstances; and if it is possible for the students to be properly instructed under the impediments which at present are reported to exist in obtaining a proper supply of bodies.

I have the honour to be,

Your obedient servant,

ANTHONY WHITE, *President*.

Nov. 18, 1834.

CLINICAL LECTURE

ON

DISEASES OF THE MAXILLARY ANTRUM.

Delivered at St. George's Hospital, Nov. 11, 1834,

By SIR B. C. BRODIE, BART.

MEMORY OF PROPER NAMES.

FUNCTION OF THE CORPORA STRIATA.

At a meeting of the Académie de Médecine on the 25th ult., M. Rouchoux made some remarks relative to M. Roux's recent allusion to Scarpa's brain. He said that the craniologists were answerable for quite enough of errors, without having others imputed to them with which they had nothing to do. M. Roux had said, that the corpora striata in the brain of Scarpa were found deeply diseased, and that this fact was connected with his forgetfulness of proper names. But anatomical examinations had generally shewn, that the corpora striata were sound in persons who had lost their memory, whilst they were often in a highly morbid state in subjects who had suffered no such loss. M. Castel observed, that partial forgetfulness of proper names had no connexion whatever with lesion of this or that part of the brain. When the memory was at all at fault, it was most commonly with respect to proper names, which are more difficult to remember than other words. Thus Broussonnet could never recollect the name of Desfontaines, whom he much prized; nor that of Bose. M. de Maran, formerly secretary of the Académie des Sciences, had the same peculiarity. M. Roux, in reply, protested against being supposed to place in necessary connexion loss of memory and lesion of the corpora striata; he had merely brought the two facts together, and did not consider it as by any means proved that the one depended on the other.—*Gaz. des Hôp.*

GENTLEMEN,—I shall draw your attention to-day to a case in one of the upper wards, that of Samuel Tovey, admitted on the 1st of this month.

Eight years ago he fell down as he was walking on the slippery pavement, by which his nose, and the whole left side of his face, were bruised. Ever since he has had pain of these parts. The left side of the face became swollen; the pain increased, and matter was discharged through the nostril. Matter also occasionally made its way through one of the alveoli of the superior maxillary bone; and he continued in this state at the time of his admission into the hospital.

On the 7th November I made an incision which separated the upper lip, or rather the cheek, from the jaw; and a probe having been introduced, it appeared to me that the extremity of it came in contact with a portion of dead bone, in the situation of the antrum maxillare. I then introduced a pair of strong sharp-pointed scissors, using them in their closed state as a chisel, to break down the thin plate of bone above the grinding teeth, so as to expose the cavity of the antrum, in which I could then feel small fragments of dead bone, some of which were extracted. On the following day some other small portions of dead bone passed through the nose. There were now swelling and pain on the left side of the face, with a good deal of headache, and a frequent pulse. The patient was ordered to be purged. On the 9th, two days after the operation, he had shivering, and was delirious in the

night. On the 10th, however, he was much improved, able to get up; and to-day the report is, that the pulse is slower, easily compressed; the tongue clean; the bowels open.

Here was a patient who had met with a severe blow on the head and face eight years ago, who had been suffering ever since; and now I have made an opening into the antrum, and extracted fragments of dead bone which were lying in its cavity. No doubt there are other fragments there; and I expect that they will come away through the opening that has been made. There can be no question that, at the time of the injury, some mischief was inflicted on the bones, which caused portions of them to die, some of these afterwards coming away by themselves, while others could not be removed without this operation.

The occurrence of this case affords me the opportunity of speaking to you concerning diseases of the maxillary antrum generally. I am glad to draw your attention to this subject, because it is one of great interest, and also one of which I do not think there is in general any very clear account given by surgical writers. I may add another reason, namely, that cases of disease of the antrum are not sufficiently common occurrences for many of you to become masters of the subject by what you see during one or two years' attendance on hospital practice.

Inflammation of the Maxillary Antrum, independent of local causes.

I have seen cases, and to these I shall first call your attention, in which there appeared to be inflammation of the maxillary antrum, independent of a local cause, arising out of something in the state of the constitution, and approaching in its character a good deal to that of severe rheumatic inflammation. I do not know that I can make you acquainted with the history of the disease of which I am now speaking, better than by describing to you the circumstances belonging to a particular case, of which I happen to have preserved notes. I was consulted with Mr. Clough, of Norton-Street, respecting a young man who complained of excessive and constant pain, referred to the situation of the maxillary antrum of the left side. There was some degree, but not much, of tumefaction of that side of the face; tenderness in the situation of the antrum every where; the very severe and constant pain which the patient endured being aggravated by pressure. In addition to these local symptoms, there was a good deal of febrile excitement of the general system. The disease had existed for two or three weeks, gradually increasing up to the time of my

being consulted. Believing this, then, to be a case of inflammation of the maxillary antrum, and thinking it not improbable, from the time that the inflammation had lasted, that suppuration might have already taken place in the cavity, I made a perforation into it above the second molaris. (I shall speak of the manner of making the perforation presently.) No fluid, however, of any kind escaped through the aperture. I then recommended what I had found successful in some other cases, that the patient should take pills composed of two grains of calomel and half a grain of extract of opium, three times daily. In about three days the gums were a little sore, the pain began to abate, and at the end of three or four days more the symptoms had entirely subsided. I believe that, when you are called to a case of this kind, you will seldom find the plan of treatment which I have here described to fail.

But inflammation of the membrane lining the antrum may end in suppuration, so that there may be a collection of pus in the cavity of the antrum, and I conclude that such acute inflammation as existed in the case just described might terminate in this manner, if not artificially arrested.

Inflammation of the Antrum dependent on local causes.

However, where matter forms in the cavity of the antrum, I certainly believe that in most instances there is some local mischief first, and that suppuration of the membrane lining the antrum supervenes as the consequence. The cause in which the disease originates is generally a diseased tooth. The patient has a bad tooth in the upper jaw, one of the molares, or perhaps one of the bicuspides (or it may even originate in the cuspidatus when the fang comes near the antrum.) The tooth is carious, and by and by the patient has the toothache. He does not like either to lose the tooth, or to submit to the pain of having it drawn, and so he submits to the toothache. The inflammation on which the toothache depends then terminates, as it always does, in the death of the pulp of the tooth. Then the whole tooth dies, and it is now like a portion of dead bone, or any other foreign substance, stuck in the jaw. Such a dead tooth may remain in the jaw for many successive years, exciting no irritation, and leading to no mischief. In other cases, however, the tooth begins, even at an early period, to operate as a cause of irritation, and it almost invariably does so ultimately. Then inflammation takes place at the bottom of the alveolus, and is followed by suppuration. The matter cannot readily escape; perhaps it makes its way downwards between the tooth

and the alveolus, and presents itself in the gum, forming a kind of gum-boil. At other times the tooth is so firmly wedged in the alveolus, that the abscess cannot find its way in this direction. Under these circumstances it collects at the bottom of the alveolus, and occasions the patient extraordinary pain and suffering. The matter lying upon the bone destroys the periosteum lining the alveolus; the bone itself becomes absorbed; and the inflammation extends to the mucous membrane lining the antrum. Sometimes a small fragment of bone in the neighbourhood loses its vitality, and there is then a piece of dead bone separating the alveolus from the antrum, and producing suppuration in this cavity. Thus there is an abscess in the antrum, with a splinter of dead bone above, and a dead tooth also at its inferior part. While this process is going on, the patient suffers at first an extraordinary degree of pain from the matter pent up at the bottom of the alveolus; afterwards, when the antrum becomes affected, he complains of a dull constant pain in the cheek, with the addition of certain lancinating pains coming on as an aggravation of the pain which is constantly endured. There is then an effusion into the soft substance under the skin, rendering the face on that side oedematous, with a slight degree of red discolouration on the surface; and the patient may remain in this condition for a great length of time. In some cases matter is discharged by the nostril, but not always, for the inflammation of the antrum may have the effect of stopping up the orifice where it communicates with the nostril, between the two turbinated bones. When the opening of the antrum remains pervious, the patient will, of course, experience occasional relief from the matter passing into the nostril. I have said that sometimes there is, and sometimes there is not, a fragment of dead bone; but this, as far as I know, makes no difference in the symptoms, although, when there is dead bone, the recovery of the patient may be expected to be more difficult and tedious.

Treatment.—In these cases you may relieve the symptoms for a time by applying leeches to the cheek, by the exhibition of purgatives, and by adopting what is called an *antiphlogistic* treatment of other kinds. But it is evident that such antiphlogistic treatment can only *relieve* the symptoms—it cannot strike at the root of the disease.

The first thing to be done is to extract the dead tooth; and it may be that this is all that is wanted. If, when the tooth is drawn, there is a free communication between the alveolus and the cavity of the antrum, the matter is discharged through the opening, and the patient is immediately

relieved. In other cases, however, when the tooth is drawn, either the abscess of the antrum does not discharge itself at all through the aperture, or it does so only in an imperfect manner. The plate of bone between the alveolus and the antrum is generally very thin, and you may easily introduce a sharp-pointed instrument into the bottom of the alveolus after the tooth is extracted, and break it down, so as to establish the communication which is wanted. This must always be done whenever the extraction of the tooth does not leave any or a sufficient opening for the discharge of the matter from the cavity above.

The instrument with which you make the opening should be formed like a common hydrocele trocar, but a little larger (of course without a canula), and it should not be made of the best steel; for I once used a common trocar, made of steel, in an operation of this kind, and it broke while I was performing it. In this case, I extracted the broken portion very easily, but you can conceive that such an accident might occur, and you might experience great difficulty in extracting the point of the instrument. The steel, then, ought not to be very finely tempered, but such as would bend a little instead of breaking. There is no occasion for its being otherwise; for you do not want a very sharp-pointing instrument. It is sufficient if it be strong, and will not easily break.

When the bottom of the alveolus is broken down, the matter will readily escape from the antrum, and you may introduce a probe and explore its cavity, so as to ascertain whether there be in it any dead bone or not. Sometimes there is a piece of dead bone at the bottom of the alveolus, and then you have only to wait patiently till an opportunity occurs for its removal. At other times you will feel the dead bone after the probe has entered the antrum, and the opening already made may not be sufficient for its extraction. Under these last-mentioned circumstances, the opening must either be enlarged or another made in a different place. When a free opening has been formed into the antrum, you should allow the patient at first to remain quiet, with a piece of bougie or gum catheter retained in it, in order to prevent its closing. This should be taken out two or three times daily, to allow the escape of the matter. After two or three days, being provided with a syringe having a slightly curved pipe, small enough to enter the opening, you should begin to wash out the cavity of the antrum by injecting some tepid water into it once or twice daily. The water injected will generally pass into the nostril,

shewing that the natural aperture of the antrum remains pervious; and if it be, then you are able to wash it out more readily and completely than you could do otherwise. If you find that the injected water does not pass out of the nose, you will know that the natural opening between the two turbinated bones is blocked up, and you will then have a little more trouble in washing the cavity of the antrum thoroughly out.

Let us suppose another case—viz. that a dead tooth has been allowed to remain until it has produced suppurative of the antrum; that it has then been extracted; that nothing further has been done; and that the patient has been left either with no opening at the bottom of the alveolus or one that is insufficient. Under these circumstances, the bottom of the alveolus becomes filled up with new bone, the edges at the inferior part are absorbed, and the alveolar cavity no longer exists. It is absolutely necessary to the patient's recovery that an opening should be made into the antrum; but where, in such a case as this, would you make it? In the situation of the alveolus? This is an awkward place for the purpose, on account of the thickness of the bone which you have to penetrate. It may be a good situation when the tooth has just been drawn, but it is a very bad one when the jaw has become consolidated afterwards. The best mode of making the opening is this: raise up the cheek so as to expose the membrane covering the gum on the side of the face, and with a scalpel make a transverse incision down to the bone. Always make this incision through the membrane before you begin to perforate the bone. In one case I did otherwise, thinking the division of the membrane, as a separate part of the operation, was unnecessary; but the consequence was, that the blood escaped into the cellular membrane beneath, and there was an immense ecchymosis, making the rest of the operation very difficult. Always, then, divide the membrane first, where it covers the jaw just above the alveolar processes of the grinding teeth, and then perforate the thin plate of bone as nearly as possible to what you suppose to have been the original seat of the disease.

What instrument is to be employed in making the perforation—a trephine? That is quite unnecessary. Nothing is better than a pair of sharp-pointed strong scissors; apply them to the bone in their closed state, using them as a chisel, and they will easily penetrate it, and go into the antrum. You have then only to press on the scissors, giving them at the same time a rotatory motion, and you will easily break away a circular portion of bone. If the

opening be not sufficient, a broader pair of scissors may afterwards be used to enlarge it; which you may do easily, so as to make it of almost any dimensions. That is the way in which I performed the operation the other day, and you know that the finger easily penetrated through the opening thus made into the cavity of the antrum. The opening being completed, you may introduce a probe or your little finger, to ascertain if there be any dead bone. As the soft parts contract, it will become necessary for the patient to wear a plug in the orifice, to prevent it being closed. A piece of ivory or box wood answers the purpose very well. The plug should be conical in shape, so that it may not slip into the cavity of the antrum. It should be withdrawn twice daily, and a little tepid water injected into the antrum to wash it out. This practice may be continued as long as the discharge of pus continues, or as long as you have reason to suspect that there is any dead bone to come away.

In some cases the patient recovers perfectly after the operation, and in others not. A lady consulted me, who had had symptoms of abscess in the antrum for many years, being otherwise in very ill health, and there was the greatest reason to attribute her ill health in part to the putrid matter collected in the antrum passing through the nostril into the fauces, and being swallowed during sleep. There was a carious tooth, which was extracted, and I then made a wide opening from the bottom of the alveolus into the antrum, and let out a good deal of pus. A plug was kept in the opening, and the antrum washed out night and morning; the fluid used in the injection flowing into the nostril. No dead bone ever came away, nor was any ever felt by the probe; but, nevertheless, the suppurative discharge continued. The patient, some few years afterwards, died of disease of the lungs, and I believe that to the day of her death the discharge of pus from the antrum had not ceased. Where there is extensive dead bone which does not come away easily, of course you will understand that suppuration must continue; but here it continued although there was no dead bone—at least none was ever discovered.

Collection of Transparent Fluid in the Antrum.

The next disease of the antrum of which I shall speak, is one of more rare occurrence; in fact, I have seen only two cases, and I can only find one or two instances of the kind on record. A lady consulted me with a large projection of one cheek. It looked as though she had a

large plum in her mouth. I lifted up the cheek, and found a projection in the situation of the antrum of one side, elevating the membrane from the gum, and the flesh of the cheek also. This projection was as large as a pigeon's egg. The surface, where it was covered by the membrane of the cheek, gave way a little under the pressure of the finger. There was no distinct fluctuation, but a kind of crackling sensation communicated to the fingers, as if you pressed upon very thin horn, or dry parchment. This being the first case of the kind that I had met with, I did not know what it would turn out to be, and I thought it likely that there was some solid tumor in the antrum. I took a curved scalpel, not bent in the direction of the cutting-edge like a bistoury, but bent laterally, with a strong sharp point (which I had found very useful on some other occasions, and introduced the point into what seemed the thin bony parietes or boundary of the tumor; having previously dissected the membrane of the cheek from the jaw. Immediately there escaped a large quantity of transparent fluid, like very thin mucus; something like what we find in cases of ranula. I then introduced a probe into the cavity of the antrum, and found that it might be passed in any direction. There was neither tumor nor dead bone, and the cavity seemed to be in a natural state, except that it was enormously dilated. I next enlarged the opening, cutting out a circular portion of thin bony shell formed by the expanded parietes of the antrum. After the operation the tumor subsided, and in the course of a few weeks the cheek was not larger than the other. The aperture made by the scalpel has continued pervious to this day, though it is ten years since I performed the operation. The lady wears a plug, which she takes out night and morning, and with her own hand introduces the point of a syringe, and washes out the antrum. I suppose that there can be no doubt that, in this case, from some accidental cause, the natural aperture into the nostril had become closed, and that the mucous secretion of the antrum, having no means of escape, collected and distended the cavity to this large size. The same thing happens to the gall-bladder when the ductus cysticus is obstructed: the gall-bladder then becomes enormously distended—not with bile, but with transparent mucus.

This last summer I was consulted, with Mr. Lawrence, concerning a case exactly similar to the one which I have just described, but it occurred in a boy. Mr. Lawrence made an opening into the tumor, and let out a large quantity of transparent fluid. I have not heard of

the patient since, but I have no doubt he completely recovered.

Polypus of the Antrum.

Surgical writers describe polypi as arising from the mucous membrane of the antrum;—nay, some have gone so far as to tell you how you are to apply a ligature round the base of this polypus, so that it may wither and drop off. The history and treatment of such a polypus is, however, altogether hypothetical. No polypus, I believe, ever existed in the antrum, around which a surgeon could put a ligature; and I never heard of the operation being performed, though it has been described by some writers.

Malignant Tumors of the Antrum.

Tumors of a malignant kind, however, grow in the antrum, partaking partly of the nature of fungus hematodes, and partly of carcinoma. They are attached to the mucous membrane, and soon grow so as to fill up the cavity. I suppose that at first they produce but little pain, and that the patient has scarcely any symptoms of disease; at any rate there are no symptoms, by the description of which the surgeon would be able to recognize the existence of disease in its very early stage. But it is otherwise as the disease advances. The tumor, growing larger, presses upon the inner surface of the antrum, and causes its bony parietes to become dilated. By and by it makes a projection in the cheek, just like that which I described in the last case, where there was a collection of mucus in the antrum. After a time, there is another projection in the situation of the bony palate—that is, the tumor presses upon the floor of the antrum, as well as at the sides. Then another projection occurs at the inferior part of the orbit; and there is another still blocking up the nostril: in fact, the antrum becomes distended every where, causing an enlargement of the cheek, bringing the bony palate to a level with the grinding teeth below, and diminishing the cavities of the orbit and nostril. The bony substance of the antrum becomes absorbed under the pressure of the tumor; the base of the alveoli is destroyed; the teeth are rendered loose, so that they merely hang in the jaw by flesh, and you can extract them with a pair of forceps, or they drop out of themselves. The tumor goes on increasing until the antrum will admit of no further distention; ulceration takes place, and the malignant growth projects through the ulcerated opening. Generally it projects, in the first instance, under the cheek. A large ulcer is formed there, and the tumor appears through it. It then makes its

way by ulceration into the mouth and orbit; sometimes it pushes the eye upwards, and at other times forwards, so that it is quite out of its natural place; and in either case it occasions blindness. As the disease makes still farther progress, it forms a large tumor in the mouth, compressing the tongue, and preventing mastication.

The malignant growth having made its way externally, and being freed from the pressure of the neighbouring parts, increases at a still more rapid rate than before. There is profuse discharge, occasional hæmorrhage; and the patient is worn out partly by these causes, partly by misery and anxiety of mind, and by starvation: for now he is unable to masticate solid food; and as the destructive process of the parts in the neighbourhood goes on, there is at last great difficulty in swallowing even liquid nourishment, only a small portion of which goes down the throat, while the greater part passes out at the aperture in the cheek. I do not know any thing more miserable than the death-bed of a patient who dies from this horrible disease. Such is a brief history of its progress; but if you wish for further information on the subject, you will find an excellent and very graphic account of it in Mr. Travers's paper on Malignant Diseases, published in one of the volumes of the *Medico-Chirurgical Transactions*.

I suppose that it is this disease of which some surgeons have conceived that it might be removed by ligature. Others have imagined that it might be got rid of by other means: that we might make an opening into the antrum before the tumor acquired a very large size, turn it out with the fingers, and apply the actual cautery to the surface from which it grew. I believe there is a case recorded by Desault, where this operation was performed, and it is spoken of as being successful. But if I remember right, he gives the history of the case no later than three months after the performance of the operation; and you all know that a malignant disease may appear to be cured for a twelvemonth, and yet return. The circumstance of the patient appearing to be tolerably well three months after an operation of this kind, by no means proves that it produced a permanent cure.

I did attempt to destroy a tumor of this kind formerly, in the following manner. It was in the early stage of the malignant growth; but the cheek bulged out over the dilated antrum, and the bone of the antrum was absorbed. With a common scalpel I cut out a large portion of the membrane, which now formed the only boundary of the antrum. I then found a

large tumor, suspended, as it were, in the antrum, appearing to grow from a broad surface. The outer part of the tumor was of soft consistence, which I broke down with my fingers, and I then turned the tumor out, so that the antrum appeared to be perfectly empty. But this was not done without an enormous and indeed frightful hæmorrhage. I introduced a quantity of what we call *blue lint*—that is, lint dipped in a solution of copper, and then dried, and filled the cavity of the antrum with it, hoping that this might make the base of the tumor to slough off. Sloughs did come away, but, nevertheless, there was no destruction of the disease. I applied caustic afterwards, and the actual cautery, very extensively, but without at all checking the growth of the tumor, which went on in spite of all the plans I adopted with a view to restrain it: in short, it grew faster than I could destroy it, the cheek ulcerated, and the patient died in the miserable way that I have just described.

GUY'S HOSPITAL. CLINICAL LECTURES.

To the Editor of the Medical Gazette.

SIR,

THE abuse and misrepresentations of the *Lancet* have caused a kind of suspicion to be thrown by the public on the motives of those students who come forward as complainants; nevertheless, I feel it necessary to appeal to you for insertion of a plain statement respecting one of the surgeons of Guy's Hospital.

On the 7th October Mr. Morgan gave the surgical pupils an "introductory" clinical lecture, and a good one too. He spoke of the advantages of hospital attendance,—on the necessity of clinical lectures: he told us, that without these our education must be considered *imperfect*, even although we had attended the systematic lectures. He expressed his determination to meet us weekly, and added, that Mr. Cooper would do the same; and after making some useful observations on strumous ophthalmia, concluded by saying, "On this day week I shall meet you with some other subject." From that time to this Mr. Morgan has not given a single clinical lecture.

Now, sir, having gone round several times with Mr. Morgan, knowing his name as a writer, and being much pleased with that urbanity and willingness to communicate information which have rendered him so popular with the pupils, I confess that when I paid my 26*l.* 5*s.* I felt that Mr.

M.'s clinical lectures were no small part of the privileges I was to gain.

I have little doubt that Mr. Morgan's retiring disposition has been the obstacle to his lecturing; but I am also sure that he will see the propriety of not allowing that to interfere with what his promise at the commencement of the season has rendered an imperative duty.

I hope I may stand acquitted of intentional disrespect to Mr. M. in bringing this before his notice.

Your obedient servant,
C. C. S.

Dec. 2, 1834.

P.S. It is but justice to Mr. Cooper to say, that he has lectured regularly every Saturday.

COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS IN NOVEMBER 1834.

Alex. Ure, Charlotte Street, Bedford Square.
John Jones, Newcastle Emblayn.
Charles Bennett, Commercial Road.
John Bryden, Manchester.
William Jones, Bristol.
William Fister Moore, Preston.
Henry Dunning, Baileyburrow, Co. Cavan.
Francis Burnett, Aberdeen.
William Apjohn, Limerick.
Thos. William Trotman, Barbadoes.
Fred. H. Clark, London.
James Pattison, —
Abraham King, Bridgewater.
Henry P. Jones, Penbroke.
William Brabner, Jamaica.
Arthur William English, Hull.
Gay Shute, Mecklenburgh Square.
John Hand, London.
John L. Craigie, —
Henry Harvey, Newcastle-upon-Tyne.
John Hughes, Llanrwst.
Henry H. Harrison, —
Henry Woodridge, Winchester.
George T. Fogarty, Drogheda.

APOTHECARIES' HALL.

LIST OF GENTLEMEN TO WHOM CERTIFICATES HAVE BEEN GRANTED.

Thursday, Nov. 27, 1834.

Samuel Gamble Wilcox.
Alfred Hall, Grange-house, Derbyshire.
Nicholas McCam, London.
Robert William Smith, Bristol.
Henry Davenport, Egham, Surrey.
James Henry Wells, Cheltenham.
Robert Whitmore Clarke, Margate.
Robert Dent, Aylsham, Norfolk.
Henry Prout Jones, Penbroke.
Frederick Richard Hitch, Melbourne.
William Barnard, Bramdean, Hants.
Thomas Harwood, Boston.
Reginald Orton, Bombay.
Percival Leigh, South Cross, Minchester.

Saturday, Nov. 29.

Francis Packard, Middleton, Suffolk.
Richard Burdall Lyth, York.
Robert Craven, Wakefield.
Thomas Lavery, Manchester.

Thursday, Dec. 4.

Walter Watson, Grandbro', Warwickshire.
James John Garth Wilkinson, Warwickshire.
Edward Pope, Chippenham, Wilts.
John Smith, Wigton, Cumberland.
James Titterton Jameson, Ashton-in-the-Wil-
lows.
James Watson, Sheffield.
John Charles Atkinson, Sheffield.
John Orton, Earl Shilton, Leicester.

LECTURE XI.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

PERIPNEUMONIA.

Signs of Engorgement.

WE now proceed to consider the signs of peripneumonia, detailing them in relation to the order in which we have described the anatomical stages of the disease.

Local Signs.—1st. *Engorgement*—*Crepitation*.—The lung in the first stage of inflammation is gorged with sanguineous serum. You recollect the proposition I advanced in treating of auscultation—that whenever fluid, combined with air, existed in the tissue of a lung, it produced a crepitating sound. This sound is pathognomonic of engorgements. It is analogous to the bursting of a number of small, equal-sized, and slightly humid bullæ in rapid succession: it is exceedingly distinct, if the engorgement be near the surface of the lung, but becomes much less so, if it be an inch or two from it; if farther still, the crepitus is no longer heard: so that it sometimes occurs, when the inflammation commences in the centre of the organ, that no local signs whatever are appreciable, although the functional and general symptoms of peripneumonia be present. It, however, almost invariably happens that the engorgement arrives ultimately at the pulmonary surface, often

in a few hours, or, at most, in a day or two, and then the crepitation, which was masked by the sound of the respiratory murmur, becomes perfectly distinct, and the disease is no longer latent or obscure.

The crepitation is heard first in the lower lobes of the lungs, because the engorgement begins there. As hepatization commences, the bullæ seem more humid, are less equal in size, and succeed each other with less rapidity. The respiratory murmur gradually diminishes, till it finally ceases with the crepitation, as the organ solidifies.

Percussion.—If the engorgement occupy but a small portion of a lobe, then there is no difference in the sounds on percussion; indeed, if even the engorgement be considerable, it requires an experienced hand and ear to detect a difference, because the inflamed lung still contains a considerable quantity of air. As the liver often mounts high in the chest on the right side, no inference ought to be drawn from eliciting a dull sound from the inferior ribs of that side, as it may depend upon the presence of that viscus, as I have before explained.

2d Stage—*Hepatization.*—Neither the natural respiratory murmur nor crepitation can now be heard, because no air exists in the vesicles to produce the first sound, nor is there a mixture of air and serous fluid in them to produce the second. Occasionally *bronchophony* takes place, particularly when inflammation attacks those parts of the lungs where the bronchial tubes are the largest, as at their roots or upper lobes: this phenomenon is very evident when the disease appears at the surface of the organ, and is indistinct when in the centre.

When, combined with hepatization, a thin layer of fluid is interposed between the pleura, the bronchophony becomes louder, in consequence of its combination with *egophony*. These sounds are always most distinct at those points of the chest which correspond to the roots of the lungs, because there the bronchial tubes are largest;

but as these tubes become of less diameter in the inferior lobes, there the bronchophony is less audible.

The bronchial respiration and cough always accompany bronchophony; sometimes these sounds are heard when the latter is not. It appears that the two first signs may be distinguished when the hepatization is deep-seated, but the union of the whole only when it is superficial.

The solid lung renders the wheezing incident to accidental co-existing catarrhs much more distinct.

When the hepatization surrounds a large bronchial tube near the surface of the organ, particularly at its roots or superior lobes, then the bronchophony simulates pectoriloquy, and is often also accompanied by the sensation of blowing into the ear, described in the lecture upon auscultation. If a slight portion of non-hepatized lung be placed between the parietes of the chest and the resonating tube, then the "souffle voilé" is heard.

As the inflammation extends, the crepitation extends also. Thus the signs of engorgement will occur in the first instance in the lower lobe, to give way to those of hepatization; then they will be heard surmounting the parts hepatized, to give way also to those of consolidation; and so on successively, until the whole of the lung becomes solidified.

In consequence of the power of respiration being lost in the inflamed lung, the necessity for respiration increases in the other, so that in the latter the respiratory murmur becomes extremely loud, constituting the *puerile* respiration. This condition of the respiratory murmur in the healthy lung is always distinct in proportion to the extent and completeness of the hepatization.

The sound is dull upon percussion, except the disease attacks the centre of the lung, and then sufficient air will be interposed between the solid parts of the organ and the parietes of the chest to produce a good sound. Percussion on the lower part of the right side of the chest cannot be depended upon, from the presence of the liver, as I have before indicated. If, however, you have been enabled to follow the disease from the state of engorgement, then you can unhesitatingly say, if the sound be subsequently dull, that it depends upon hepatization, and not upon the presence of the liver.

3d Stage—Purulent Infiltration.—There are no local signs of this state differing from those of hepatization. The same physical state exists here, as far as relates to the solidification of the lung, and consequently the same physical signs present themselves.

4th Stage—Purification.—But when the con-

crete pus softens, and is evacuated, at the point of the chest corresponding to the vomica a noisy mucous rattle occurs, which is gradually transformed upon inspiration and coughing into a cavernous sound. Pectoriloquy also appears. The sensation of blowing to and from the ear occurs, if the abscess be near the parietes of the chest, and the "souffle voilé" becomes distinct, if the walls of the cavity be thin and soft, and not adherent to the costal pleura.

5th Stage—Gangrene.—I have met with fourteen or fifteen instances of gangrene of the lung, and in every case crepitation was discoverable; doubtless, because of the accompanying engorgement of the lung. When the organ commences to break down and form an excavation, then the mucous rattle is very audible; it gives way at last to complete pectoriloquy, with cavernous rhonchus and cough. If the excavation opens at once into the bronchi and pleura, then the metallic tinkling, or the amphoric resonance, are produced.

Local Signs of the Resolution of Peripneumonia.

1st Stage—Engorgement.—You will recollect, gentlemen, that when resolution of the engorged lung occurs, that the red-coloured serum gives place to a colourless fluid infiltrating the air-cells; consequently, although the inflammation has diminished, or even disappeared, yet the crepitation will remain for some time; it finally, however, becomes less distinct, until at last it totally disappears, leaving the sound of the natural respiratory murmur.

2d Stage—Hepatization.—When resolution takes place from hepatization, you will remember also that the solidified lung returns into a state of serous engorgement; the crepitation will therefore reappear, constituting the "*rhonchus crepitans redux*" of Laennec. This sign, accompanied by the re-appearance of the respiratory murmur, and the absence of the dull sound on percussion, is pathognomonic of the resolution of hepatization.

3d Stage—Purulent Infiltration.—Laennec asserts that the rhonchus crepitans equally announces the resolution of the disease even in this state, but that it is ordinarily preceded by mucous or sub-mucous rattle, indicating the softening of a part of the pus. He says, also, that the respiratory murmur always appears more tardily.

When peripneumonia has attacked a large portion of the lung, the resolution occurs first in those parts which were the last affected. The resolution has sometimes, although I believe very rarely, taken place in the inverse order.

4th—Purification.—We know but too little of this stage to be able to give the exact signs

of its resolution. There can be but little doubt that when it does happen, all the signs previously described must gradually disappear, and give way to the natural respiratory murmur.

5th Stage—Gangrene.—Resolution may take place even in this stage: the serum engorging the lung totally disappears, and with it its sign of crepitation. I have found pectoriloquy disappear also—no doubt from the union of the sides of the gangrenous excavation. A young sailor, in the wards of this hospital, was the subject of this formidable disease: we were enabled to trace all the signs, almost from the commencement, to excavation of the pulmonary substance. In four or five months he was discharged. In a year afterwards he returned from a voyage, and presented himself at the hospital in robust health. The previously existing pectoriloquy had completely disappeared.

Functional Signs of Peripneumonia.

Pain.—This is a very uncertain symptom: sometimes it occurs, sometimes it does not; when present, it usually is deeply seated, and of considerable extent; occasionally it is found only in a fixed point, and if it be acute it generally arises from pleuritic combination.

Dyspnea.—This symptom varies according to the quantity of lung affected: if the inflammation be slight, the number of respirations are but slightly increased; if it be very extensive, I have seen, especially in children, the number augment to sixty or seventy in a minute, and the distress and danger of suffocation then become extreme.

Cough is often present, although occasionally it is so slight that the patient does not notice it.

Expectoration.—When expectoration takes place—for it is not of constant occurrence—it becomes so characteristic, that Laennec believed that from it alone the disease might be detected. The sputa, which he calls *glutinous* or *pneumonic*, collected in a flat open vessel, as a plate, form a mass so tenacious and viscous that if the vessel be reversed when full, the expectorated fluid separates, or is detached from it, with difficulty: it trembles, something like a jelly, upon agitation. The colour of the sputa varies—it may be red, or rusty, sea green, orange, saffron, yellow, or of a dull green: these colours are often intermixed. The expectoration “en masse” has something of the transparency of horn, or of white of egg slightly coloured; it contains bullæ of air of unequal size, and in large quantities. This state of expectoration seems to take place only in the first stage of peripneumonia or engorgement.

But these characters are not always so distinct, for sometimes the sputa are less viscous, less coloured, and less spumous; at others, a small quantity of fawn coloured glutinous matter may be seen mixed in a considerable mass of mucous or pituitous fluid: occasionally these glutinous sputa occur only in the beginning of the disease, and then but in small quantity.

During hepatization, the sputa vary in appearance: they are composed of viscous pituita, or white or semi-opaque yellow mucus: they are still more mucous in character when purulent infiltration supervenes; sometimes mixed with yellowish stræ, indicating, probably, the presence of pus: rarely, indeed, is the whole of the matter expectorated puriform.

The expectoration in gangrene of the lung is so characteristic that when once met with, it will be impossible to mistake it; for the odour is so fetid and peculiar that it is almost insupportable. I have known the breath of a patient infect the air of the whole house, so that it was hardly bearable by its inmates. The colour of the gangrenous sputa varies exceedingly: it is sometimes of a bright yellow, or green, brown, or of a milky white. I have seen, in two instances, a yellowish green substance, mixed in streaks or large spots, with a matter as black as ink. The consistence of the expectoration is that of pus, although sometimes it is much thinner.

General Signs of Peripneumonia.

1st Stage—Engorgement.—It is to this state of the lung that the term inflammatory ought, I think, really to be restricted, for hepatization, purulent infiltration, and vomica, are merely consequences of engorgement, as much as abscess is a consequence or termination of subcutaneous cellular inflammation. The general as well as local signs of engorgement are also very different from those of the other stages of peripneumonia.

Thus this stage is ushered in by an access of acute inflammatory fever, usually intense, except the peripneumonia be slight and partial. The face becomes coloured of a vivid red in the first instance: if the disease be severe, the redness becomes mixed with a livid, slaty, or bluish tint, consequent upon venous congestion. The pulse is rapid, full, and hard; the blood usually presents a thick buffy coat, and the crassamentum assumes a cup-like form. As the inflammation extends, various congestions occur, but principally towards the cerebrum, so that delirium is often induced in young persons, coma in old, and convulsions frequently in children. The tongue is often intensely red, which, according to Broussais, indicates

gastric sanguineous congestion or inflammation. The urine is high coloured, and small in quantity, and towards the termination of the febrile symptoms, diarrhoea occasionally supervenes.

This symptomatic fever ceases upon the diminution of the inflammation of the lungs. If, however, the febrile state depends upon other co-existing causes, or if it be of the character called essential, then it often remains with unabated force after the peripneumonia has diminished or even ceased.

2d—Hepaticization.—Usually, the inflammatory fever now disappears, and dyspnoea alone remains, although commonly with diminished intensity: the difficulty of breathing also soon ceases, as the resolution of the hepaticized lung takes place. But it will occasionally happen, gentlemen, that you may meet with cases supposed to be consumptive, but in which the symptoms depend upon the long duration of the hepaticization: thus there is dyspnoea, cough, expectoration, emaciation, an habitually rapid pulse, a slight fever in the evening, and even occasionally night sweats, although rarely so profuse as in phthisis. Examine your patient, and you will now find the value of auscultation, by discovering that there are no local signs of tubercular disease, but that one or other of the lungs is hepaticized, perhaps to half or more of its mass. This state is often *curable*, and I have no doubt that many patients have been considered to have recovered from pulmonary phthisis, when they have really only been affected with hepaticization of the lungs.

3d and 4th Stage—Purulent Infiltration and Vomica.—The general symptoms of these states have not been sufficiently observed, but most probably they are similar to those of chronic hepaticization.

5th Stage—Gangrene.—The general signs of gangrene vary; for they may be of exactly opposed characters: thus, when the disease attacks the young and plethoric, it may be accompanied by all the symptoms of inflammatory fever; if the weak or aged, it may be, and is most commonly, combined with a general asthenic condition of the system, indicated by extreme prostration of strength, and great anxiety. I have frequently seen the dyspnoea very slight, and bearing no proportion to the extent of the local, or the intensity of the general signs.

Combination of Peripneumonia with other Diseases.—Peripneumonia may be combined with pleurisy, with hæmoptysis, and with œdema pulmonum; all of which complications we shall speak of when we arrive at the consideration of these diseases.

The sero-sanguineous congestion of the

lungs, which occurs so commonly in the agony of death, is often transformed into peripneumonia, if that agony be long.

Peripneumonia and catarrh are not unfrequently combined; this combination often prevailed in the influenza of last year, and in that of 1803. This is the *peripneumonia notha* of the old authors.

Tubercular disease is occasionally accompanied by inflammation of the lungs. This will be particularly indicated by the supervention of any sudden and unusual febrile attack upon the ordinary symptoms of phthisis; it is accompanied also by as sudden an increase of the dyspnoea.

There are few fevers in which peripneumonia may not occur during their course, as in measles, particularly towards the disappearance of the eruption; in the course also of confluent small-pox, or erysipelatos fevers. I have seen peripneumonia come on during the progress of continued fevers, either of the synchoid or typhoid forms, and such complications are by no means infrequent.

Inflammation of the lungs occasionally takes place during the course of pertussis; two years ago this complication existed epidemically.

Causes of Peripneumonia.

Individual.—Although the disease is always more intense in young persons of sanguine temperaments, yet it appears to occur much more commonly in old people, in whom, according to Laennec, it runs much sooner into the suppurative stage.

Peripneumonia very frequently attacks infants; it usually exists then in the lobular form, and the disease is generally fatal to them in the stage of engorgement.

External.—The external causes are the same as in those of other inflammations—as cold, sudden changes of temperature, &c. The bite of the rattle-snake is said to induce inflammation of the lungs. The disease is most common in winter.

The causes of gangrene of the lung are at present hidden in the most complete obscurity. I believe I can say to a certainty that it is not a contagious disease.

Treatment of Peripneumonia.

I shall speak of the various remedies that have been employed in what I conceive to be the order of their importance.

1st Stage—Engorgement.—Bleeding.—There is scarcely any remedy so powerful in its effect upon peripneumonia as bleeding. It is in the stage of engorgement, particularly when accompanied by general febrile excitement, that blood should be abstracted promptly and freely, and you will find, even as it flows, that the dyspnoea will diminish, and the patient express

himself relieved. It is the practice in this country to bleed the patient in an upright posture, and to make a large orifice in the vein, so that fainting may be speedily induced. Experience has shewn that a greater impression is made upon inflammatory diseases by this method, and that a cure can be thus effected by a less loss of the vital fluid than if a larger quantity be abstracted in a small and slow-flowing stream. It often happens after a single bleeding, that the dyspnoea recurs with febrile reaction, and a full pulse; it will then be necessary to repeat the venesection, perhaps even three or four times, before the inflammation be subdued. It is impossible to give any other general rule as to the extent you may bleed, but that you must be guided by the intensity of the symptoms, and by the strength of the individual.

Leeches and cupping may frequently be used with advantage, when the weakness of the system contra-indicates a general bleeding.

Tartar Emetic.—Antimony, in its various forms of preparation, has been long used in medicine, and as an emetic, particularly, in peripneumonia. But it was reserved for Rasori to point out the special advantage of the tartar emetic in inflammation of the lungs. I shall not enter here into the theory of *contra stimulus*, by which he attempts to explain its action, but proceed at once to the description of the mode in which you should use it, premising by saying that there is no medicament so decisive in its action in combatting this disease.

Laennec, immediately after bleeding his patient, gave a grain of tartar emetic in two ounces and a half of a slight and cold infusion of orange flowers, sweetened with half an ounce of syrup of mallows, or orange flowers. He repeated this dose every two hours, until the patient had taken six grains, and then suspended the use of the remedy for seven or eight hours, if the symptoms were not urgent, or there was a disposition to sleep. If the symptoms were distressing, and the head became affected, he repeated the medicine in the same way, until an amelioration took place, sometimes, in severe cases, gradually increasing the dose to as much as two grains and a half.

Many patients bear the tartar emetic without its producing either vomiting or purging: most, however, vomit two or three times, and are purged during the first day, but commonly afterwards they tolerate the remedy perfectly. If they do not, then the addition of a little syrup of poppies, or a few drops of the tinct. opii, with the first few doses, occasions it to be borne easily.

If the first dose produce vomiting, the

subsequent doses will doubtless often produce the same by mere association of ideas, and the patient will have considerable repugnance to taking his medicine. It is best to obviate this: I therefore, after freely bleeding, commence with one-third of a grain of tartar emetic in half a wine glass full of water, adding a few drops of tinct. opii, or syrup of poppies. I give two doses at the interval of one hour from each other; I then increase the quantity by another third of a grain for the next two succeeding hours, omitting the opiate, if no sickness be induced, and so on successively, by the addition of a third of a grain every two hours, until I arrive at two grains. I have not exceeded that quantity, although I have continued it for many days without producing any injurious effect.

You will often find, gentlemen, in following this plan, the disease will be considerably relieved in three or four hours, sometimes, however, not for twenty-four or thirty-six hours: according to my experience, the tartar emetic always acts best when it produces no effect except upon the inflammation itself; that is, when it occasions neither vomiting, purging, or depression of the powers of the system. It has been supposed by many, but erroneously, that it cannot subdue the disease except by previously producing these effects.

There is, perhaps, no stage of peripneumonia in which the tartar emetic may not be employed with some advantage, but it is certainly of most use during the engorgement of the lung. You will be called, gentlemen, to cases in which bleeding, perhaps, has been already carried to its fullest practicable extent, or where, in old and cachectic persons, venesection is no longer admissible; then you will find the tartar emetic, carefully administered, produce frequently the most astonishing curative effects. I have frequently left patients under the impression that their recovery was almost impossible, and yet have found that the continuous use of this medicament has snatched them from the jaws of death.

Laennec recommends that the tartar emetic should be continued until all signs of crepitation be merged into the natural respiratory murmur. This is not my practice: I am guided by the cessation of dyspnoea alone; for as he has himself observed, a non-inflammatory serous infiltration of the pulmonary tissue will supervene, and give rise to crepitation, after the inflammatory engorgement has totally disappeared.

Mercury.—Before I had occasion to see the admirable effects of tartar emetic in the first stage of peripneumonia, I freely employed mercury after bleeding: this

remedy sometimes produced a good effect, but it very frequently did not: it, however, is of great use when the lungs become hepatized, as I shall presently describe. In comparing the effects of tartar emetic and mercury upon acute inflammations, I have no hesitation, in saying that the first seems to act most energetically upon those of the parenchymatous tissues of the organs, the second upon those of the serous membranes.

Blisters.—Counter-irritants ought not to be applied in the first stage of the disease, especially if there be much febrile irritation; they only tend to increase the distress, and produce rarely any effect in diminishing the dyspnoea: when, however, the heat of the skin diminishes, the pulse becomes less frequent and full, and a sense of infaturation or oppression exists in the chest, with difficult expectoration, then blisters, or other counter-irritants, are of great utility.

Evacuants.—It is useful to keep the bowels gently open, but free purging is rarely of service. Emetics were formerly employed, and, it is said, with much success; but, most probably, that success must have arisen in cases where the peripneumonia was combined with derangements of the digestive organs.

Alkaline Plan.—Under the supposition that inflammation depended upon a certain plasticity and thickness of the blood, alkalies were proposed for the purpose of attenuating that fluid: thus the subcarbonates of potash, soda, and ammonia, medicinal soaps, the purgative neutral salts, were administered; but these remedies, as well as the plastic theory, have become obsolete: the polygala virginiae has also been highly vaunted, but I have never seen it produce any good effect.

Expectorants.—The ipecacuanha is an useful expectorant in all the stages of peripneumonia, especially in children: the squills or ammoniacum should not be used except in old or cachectic persons, and then only towards the resolution of the disease.

Regimen.—The regimen during the state of engorgement must be strictly antiphlogistic; no stimulants should be given, but the patient should have a free supply of cool drinks. The room ought to be kept cool, for if its temperature be high it will certainly tend to aggravate the disease. I need not say that the most perfect repose should be enjoined, and that the patient should be permitted to speak as little as possible.

Hepatization of the Lung.—Hepatization of the lungs occasionally becomes a chronic affection, lasts for many weeks, and produces a train of symptoms simulating frequently phthisis. You will recollect, gen-

tlemen, that in this case the air-cells are filled with a solid matter, and our first indication is to occasion its absorption. I have tried the tartar emetic, iodine, and mercury, with this view, but I have found the last incomparably the best remedy, if properly administered.

As the constitution is usually much impaired in this state of the lung, when the disease has become chronic, and as there is frequently a strong tendency to gastric and intestinal irritation, you will find the blue pill in five grain doses, combined with a third of a grain of opium, three times a day, one of the best means of affecting the system: if, however, there be purging, then rubbing in the mercurial ointment is still better. These means should be carried on until the mouth be rendered slightly tender, and it should be kept so for two or three weeks: the remedy should be then discontinued for a week or two, otherwise it will irritate and exhaust the patient; you will then recommence it, and this alternating plan must be carried on until the resolution of the lung be complete.

The patient during this time should have a moderately nutritious diet: thus I allow a little meat once a day, and a free use of milk, but no other drink stronger than water. You should watch closely the state of the circulation, general appearance, and dyspnoea, so that if the pulse becomes full, and the difficulty of breathing increases, a few ounces of blood may be abstracted, and the diet diminished, endeavouring thereby to establish an equilibrium between the quantity of blood sent into the lung and the quantity of air the cells contain.

The next circumstance you should attend to, is to keep your patient in the most perfect state of repose, both in mind and body; allow no exercise, otherwise the blood will be driven into the diseased lung with too great rapidity: indeed, I always endeavour to make the patient understand the nature of his case, the objects I have in view, and consequently the positive necessity of absolute repose, and you will generally find he will readily submit.

Counter-Irritants.—I usually also keep a blister open from time to time on the surface of the chest of the side affected.

Gangrene of the lungs requires two modes of treatment, varying according to the general state of the system. In some cases, although the least frequent, it is accompanied with inflammatory fever, and then you must treat it on the antiphlogistic plan. But when you meet it combined with great asthenia, then the affection must be treated upon the tonic and stimulating methods, as by wine and bark, &c.

THE ANATOMY AND PHYSIOLOGY
OF THE LIVER.

By FRANCIS KIERNAN, Esq.

Member of the Royal College of Surgeons, late
Teacher of Anatomy.

[Continued from p. 332.]

Of the Hepatic Veins, and of the Hepatic-venous Canals.—The hepatic veins are contained in canals, which may be called the hepatic-venous canals; they commence in the interior of the liver, and terminate at the fissure of the inferior cava. Those containing the hepatic trunks are formed by the capsular surfaces of a limited number of lobules; those containing the sublobular-hepatic veins, are formed by the basis of all the lobules.

As three vessels are contained in each portal canal, and as a branch of each vessel makes its exit from the canal at each interlobular space, each vessel necessarily forms a plexus, by which it is brought into apposition with all the spaces on the surface of the canal: but one vessel only, an hepatic vein, being contained in each hepatic-venous canal, the external surface of the vein is in contact with, and connected to, all the lobules forming the parietes of the canal, the intralobular veins, at their exit from the lobules, entering the sublobular-hepatic veins without uniting in the canals to form branches similar to the vaginal branches of the portal vein, duct, and artery. The interlobular branches of the vein and artery conveying blood to the lobules, correspond to the intralobular branches of the hepatic veins, which convey the blood from the lobules; the former arise from the vaginal branches, the latter terminate in the sublobular-hepatic veins. Thus we find that the hepatic veins have no branches corresponding to the vaginal branches of the duct, portal vein, and artery; and as Glisson's capsule is composed of the vaginal vessels ramifying in cellular tissue, we consequently find nothing similar to this capsule around the hepatic veins, these veins having no vaginal branches. In the smaller portal canals, in which the spaces are less numerous and the plexus less complicated, one side of the portal vein is in contact with the parietes of the canal. On this side the interlobular branches arise immediately from the vein, and the cellular tissue is in small quantity, forming a delicate membrane on the walls of the canal; on the opposite side, which is separated from the walls by the duct and artery, vaginal branches arise from the vein, and the cellular tissue is abundant. (Fig. 1.; see our last No. page 332, and

also Fig. 5, to be given in our next.) These smaller portal veins resemble the hepatic veins on that side on which they are in contact with the walls of the canal, on which no vaginal branches are given off, on which the interlobular branches arise immediately from them, and on which there is no capsule; they resemble the larger portal veins on that side on which vaginal branches arise from them, and on which the capsule consequently exists. From the absence of vaginal branches on one side of these portal veins, it may be presumed, that should a portal vein be found entering the liver unaccompanied by a duct and artery, it would, like the hepatic veins, be connected to the parietes of its canal, and would, like these vessels, have no vaginal branches, and, consequently, no capsule. The structure and uses of Glisson's capsule are now fully explained, it being evident that the loose connexion of the ducts, portal veins, and hepatic arteries, to the substance of the liver, arises from the circumstance of the three vessels ramifying in the same canals; and that the adhesion of the hepatic veins to the substance depends on one vessel only being contained in each hepatic-venous canal.

Numerous minute orifices are seen on the internal surface of the sublobular-hepatic veins; these orifices are the mouths of the intralobular veins, all of which terminate immediately in these vessels. Every orifice corresponds to the centre of the base of a lobule; the number of orifices is therefore equal to the number of lobules forming the parietes of the canal in which the vein is contained. As an intralobular vein makes its exit from the base of every lobule, and as every intralobular vein terminates in a sublobular vein, it is evident that the base of every lobule is in contact with a sublobular vein, and that the hepatic-venous canals containing these vessels are formed by the bases of all the lobules of the liver. The parietes of the portal canals are also composed of lobules; but they are composed of the capsular surfaces of lobules, and not of the bases, nor do all the lobules enter into their formation as into that of the hepatic-venous canals; for, as the interlobular ducts, veins, and arteries, ramify in fissures continuous with each other throughout the liver, many of these vessels terminate in lobules situated at a distance from the trunks from which they arise, these distant lobules not contributing to form the canals containing the trunks. As all the lobules unite to form the hepatic-venous canals, and as a certain number only enter into the formation of the portal canals, it is evident that the former are more numerous than the latter.

In the description of the lobules, the

hepatic veins contained in canals were divided into two sets, into the sublobular-hepatic veins, and the hepatic trunks. The coats of the former are delicate in texture; they are transparent; the lobules and fissures are seen through them; their internal surface is studded with the orifices of intralobular veins; their canals, which are formed by the bases only of lobules, are not lined by prolongations of the proper capsule. The trunks are more dense in structure; their external coat is composed of longitudinal bands; their canals are lined by prolongations of the proper capsule, which render them opaque, the lobules and fissures not appearing through them; they receive no intralobular branches. Dense in structure, they are not adapted to receive these minute and delicate veins; their canals, therefore, unlike those containing the sublobular veins, are, like those containing the portal veins, composed of the capsular surfaces of lobules, the intralobular veins of which terminate in a neighbouring sublobular vein.

If the internal surface of the large veins, which open into the trunks, be examined, and contrasted with the internal surface of a sublobular vein, the orifices of the intralobular veins will be found less closely arranged in the former than in the latter. This appearance arises from two causes. Two or three intralobular veins, at their exit from the lobules, frequently unite and form one vein, which terminates in the large vein, on the internal surface of which will be seen one larger orifice, instead of three smaller orifices. Frequently, also, on the surfaces of these canals the capsular surfaces of lobules are seen, the bases of which enter into the formation of a neighbouring canal; no orifices, therefore, corresponding to the bases of these lobules, are found in the veins under examination.

The intralobular veins will almost invariably be found entering the sublobular veins from the centre of what has been called the red substance of the liver.

Of the formation of the hepatic-venous canals it may be said, that the smallest of the canals, and the greater number of them, are formed by the bases alone of lobules; that the next in dimensions are formed by the bases of some, and the capsular surfaces of other lobules; and that the largest are formed by the capsular surfaces only of these bodies. As the base of every lobule rests on a sublobular hepatic vein, it is evident that those lobules, the capsular surfaces of which enter into the formation of canals, are in contact with two hepatic veins.

Ramifying in fissures which are con-

tinuous with each other throughout the whole liver, the interlobular branches of the portal vein anastomose freely with each other, enveloping every lobule in a venous web: the intralobular branches of the hepatic veins, on the contrary, confined within the lobules, have no direct communication with the corresponding branches of the surrounding lobules, from which they are separated by the substance of these bodies, and by the intervening interlobular ducts, veins, and arteries, situated in the interlobular fissures; and one intralobular vein can be injected from another only through the medium of the intervening portal veins. When injected with mercury or size, the intralobular veins appear in the centres of the lobules in the form of points, stellar, or twigs; these veins, therefore, unlike the interlobular portal veins, do not anastomose with each other. If, by means of a pipe and glass tube, mercury be thrown into a large hepatic vein on the surface of a section, it will return by several smaller neighbouring hepatic veins, which, generally, are branches descending to terminate in the larger vessel in which the pipe is fixed. If these vessels be tied, the mercury will return by large hepatic veins, situated at a distance from the injected vessel, and not branches of it. In this experiment the force used is not sufficient to propel the mercury through the intervening intralobular, lobular, and interlobular veins, and by such means to form a communication between the two hepatic veins; for if force sufficient to effect this were used, the mercury would return by portal as well as by hepatic veins, which is not the case. If the inferior cava be opened at its posterior part, and if by the same means mercury be thrown into a small hepatic vein, it will immediately return to the cava by other hepatic veins, without appearing in the superficial intralobular veins, and without passing into portal veins. From these experiments it appears that the sublobular veins anastomose with each other, and that their intralobular branches do not.

By contrasting the hepatic veins with the portal vein, we find that no two intralobular branches of the former anastomose with each other; that the interlobular branches of the latter form one continuous plexus throughout the whole liver; that the sublobular veins anastomose directly, and not through the medium of the intralobular branches; that the portal veins have no direct communication with each other, but anastomose by means of their interlobular branches; that the hepatic veins, like the other veins of the body, proceed in a direct course to their termination in the cava; that the portal vein, ac-

accompanied by an artery, resembles an artery in its ramifications; that the larger hepatic veins, having longitudinal fibres in their coats, differ in structure from the portal vein; and that the blood contained in the liver after death is almost invariably found in the hepatic veins, the portal vein being usually empty.

The longitudinal fibres in the coat of the larger hepatic veins are similar to those in the coats of the iliaes and inferior cava, and to those which are occasionally seen in some superficial veins. Those of the iliaes and cava have been delineated by Senae, who says they are composed of muscular fibres. This opinion, which was adopted by Portal, is sufficiently refuted by the existence of similar fibres in the hepatic veins, which, being firmly connected to the substance of the liver, admit of no motion.

The hepatic veins in the *Seal* differ in many respects from those of any other animal I have examined. The intralobular veins at their exit from the lobules do not, as in other animals, terminate immediately in the hepatic veins: these vessels enter the hepatic-venous canals, where they unite into branches, which, like the vaginal branches of the portal vein, are connected by a fine cellular tissue, with which they form around the hepatic veins a cellulo-vascular sheath, precisely similar to that surrounding the branches of the portal vein. The structure of the two sheaths is similar, but their uses are different. That of Glisson's capsule has been explained; the capsule of the hepatic veins in the seal appears destined to admit of the muscular contractions of these vessels. The posterior cava in this animal forms at the back part of the liver a large sinus, in which the hepatic veins terminate, and which, according to Cuvier, "is connected with the power of diving, which these animals possess in a high degree." The external coat of the hepatic veins is composed of circular fibres, which in the larger vessels form a complete tunie. In the smaller vessels the fibres are arranged in the form of circular fasciuli, which are connected with each other by oblique intermediate fibres. All the fasciuli do not extend completely round the veins; some, dividing into two portions, unite with fibres from those above and below, and form other fasciuli. By contrasting the hepatic veins in the seal with those in the human subject, it would appear that the circular bands in the former are composed of muscular fibres. In man, the fibres are longitudinal; in the seal, they are circular: in the former, the vessels adhere firmly to the parietes of their canals; in the latter, they are loosely connected by

the cellulo vascular sheath in which they are inclosed. The existence of the sinus in which these veins terminate, and in which the blood accumulates during the act of diving, appears to indicate the necessity of a muscular power to propel the blood onward to the heart. Had the intralobular veins in the seal, terminated, as in other animals, immediately in the hepatic veins, these vessels would have been connected to every lobule forming the parietes of their canals, and their muscular contractions could not have taken place; the use of their sheaths is therefore evident, and different from that of the portal vein, hepatic duct, and hepatic artery. No circular fibres exist in the coats of any of the other veins of this animal.

In the *Porpoise* the hepatic veins are connected to their canals; no circular fibres are seen in their coats. Their external surface is reticulated, the ridges corresponding to the interlobular fissures, where the interlobular cellular tissue is continuous with the cellular coat of the veins. The mouth of an intralobular vein occupies the centre of each space circumscribed by the ridges.

In diving birds, Cuvier says, "all that portion of the vena cava inclosed in the liver is of very considerable diameter, and forms a kind of reservoir similar to that in the seal." I have examined some birds of this class, but have found no circular fibres in their hepatic veins.

Of the Structure of the Lobules.—The lobules constitute the secreting portion of the liver. Examined with the microscope, a lobule is apparently composed of numerous minute bodies, of a yellowish colour (imparted to them by the bile they contain) and of various forms, connected with each other by vessels. These minute bodies are the *acini* of Malpighi; his opinions respecting their structure and use are well known. Ruysch admitted the existence of the *acini*, and, more successful in his injections than Malpighi, he filled the minute vessels which are described by the latter anatomist as ramifying between these bodies; he thereby, probably, rendered the *acini* invisible, or less apparent than they present themselves in the natural state, in which they had been discovered by Malpighi, and he concluded that these minute bodies are composed of the terminal extremities of the vessels, with a certain number of which the ducts are continuous. Boerhaave attempted to reconcile the contending opinions of the two great anatomists. Ferrein successfully opposed these opinions; he demonstrated the tubular structure of the kidney, and was the first who asserted that several

other viscera, the liver, spleen, and renal capsules, "sont un assemblage merveilleux de tuyaux blancs, cylindriques différemment repliés." Mascagni says the liver is composed of cells, from which the minute biliary ducts arise, and this anatomist enters into a description of the various tunics of which these supposed cells are composed. To Müller, whose recent discoveries have thrown much light on the ultimate structure of glands, is due all the merit of the important discovery, that a gland is a duct with blood-vessels ramifying on its parietes. This anatomist asserts, from analogy rather than from actual demonstration, that the biliary ducts in the vertebrated, like those in some of the invertebrated animals, terminate in caecal extremities, which present certain differences in the manner of their arrangement in the different classes. The foliated and pinnated appearances delineated in Müller's 11th plate, and displaying, according to this anatomist, the manner in which the terminal extremities of the ducts are arranged, appear to me to result solely from partial congestion of the liver, the foliated portions being composed of the non congested opposed edges of lobules, with the interlobular ducts, veins, and arteries, ramifying between them.

The portal vein enters the liver in all the vertebrated animals, in all of which the lobules are arranged around the hepatic veins, as I have described them in man. Each lobule is composed of a plexus of biliary ducts, of a venous plexus formed by branches of the portal vein, of a branch of an hepatic vein, and of minute arteries: nerves and absorbents, it is to be presumed, also enter into their formation, but cannot be traced into them.

The hepatic ducts, commonly so called, and their vaginal and interlobular branches, constitute the excreting portion of the biliary apparatus; they are also organs of mucous secretion, being furnished with mucous follicles: the secreting portion of the liver is also composed of ducts, which form a plexus in each lobule. These plexuses may be called the lobular biliary, or secreting biliary plexuses. The ducts composing them being exceedingly minute, and always containing bile, much greater difficulty is experienced in injecting them than in injecting the blood-vessels of the liver, even in the usual manner; and this difficulty is not so easily overcome as that occasioned by blood in the vessels, for the bile contained in the excreting ducts is propelled by the injection into the secreting ducts, from which it has no exit by other vessels, and consequently opposes the entrance of the injection. This process is, to a certain degree,

facilitated by tying the portal vein and hepatic artery in the living animal, and thereby arresting the secretion of the bile. If this operation be carefully performed, the animal will survive several hours, during which time the ducts will discharge much of the bile they contained, and the liver will sometimes become almost colourless. The experiment will probably be attended with more success if performed a few hours after feeding the animal. After preparing the liver in this manner, I have frequently succeeded in partially injecting the lobules from the hepatic duct; I have also injected these bodies from the duct in the human subject, but with less success. Examined with the microscope, the injected interlobular ducts are seen dividing into branches, which, entering the lobules, divide and subdivide into minute ducts; these ducts anastomose with each other, forming a reticulated plexus. (Fig. 6.) If an uninjected lobule be examined, and contrasted with an injected lobule, it will be found that the acini of Malpighi in the former are identical with the injected lobular biliary plexus in the latter, and the blood-vessels in both will be easily distinguished from the ducts. The ducts forming the plexuses, when examined with the microscope, present very much the appearance of cells; and this appearance, which has been well delineated by Mascagni, probably induced this anatomist to consider the liver as an assemblage of minute cavities, giving origin to the ducts. The form of the lobules bears no relation to the arrangement of the ducts, the form of each lobule being always correspondent to the branches of the intralobular hepatic vein occupying the centre of the lobule. The coats of the lobular ducts, on which the blood-vessels next to be described ramify, constitute the proper secreting substance of the liver, as the coats of the cortical ducts of the kidney, and those of the tubuli seminiferi, constitute the secreting substance of their respective organs.

The left lateral ligament may be considered as a rudimental liver, in which this organ presents itself to our examination in its simplest form. From that edge of the liver connected to the ligament, numerous ducts emerge, which ramify between the two layers of peritoneum of which the ligament is composed. These ducts were discovered by Ferrein, but this anatomist did not ascertain their termination. "A l'égard des vaisseaux biliaires, M. Ferrein en a observés de nouveaux, dont les uns reviennent du ligament gauche du foye, et qu'il a vus quelquefois repandus sur la face inférieure du diaphragme." These ducts, the smallest of which are very tortuous in their course, divide, subdivide, and anasto-

mose with each other. They are sometimes exceedingly numerous, two or three of them in such cases being of considerable size; some of them, as Ferrein says, frequently extend to the diaphragm, and ramify on its inferior surface. They sometimes extend only half way up the ligament, where they divide into branches, which, forming arches, return and descend towards the liver, anastomosing, or being continuous, with other ducts issuing from it. The spaces between the larger, or excreting ducts, are occupied by plexuses of minute, or secreting, ducts. I have injected the ducts on the inferior surface of the diaphragm, but have not succeeded in injecting them to their termination; we may however conclude, that, like those just described, they form arches, the branches returning towards the ligament, and being continuous with those ascending from it. Branches of the portal and hepatic veins, with arteries and absorbents, also ramify in the ligament, which, including between its layers a plexus of secreting and excreting ducts, with blood vessels ramifying on their parietes, admirably displays the structure of the liver. Ferrein speaks of other ducts: "d'autres reviennent de cette portion des parois de la veine cave, qui paroît hors l'échancrure sigmoïde du foye quand on le regarde par derrière, d'autres enfin reviennent des membranes de la vésicule du fiel." The inferior cava usually occupies a fissure at the back part of the liver; this fissure is frequently converted into a canal by a portion of the liver, extending from the lobulus Spigelii to the right lobe; frequently, also, the fissure is converted into a canal by a band, apparently of ligamentous texture, varying in width in different subjects. This band is, like the left lateral ligament, a transparent portion of the liver, containing ducts and blood vessels. In a preparation in my possession, in which the ducts in this band are injected, a few injected ducts are seen issuing from the right lobe and ramifying on the coats of the cava above the band. The umbilical vein is also contained in a fissure, which is frequently converted into a canal by the process of the liver, called the *pons hepatis*, extending from the lobulus quadratus to the left lobe; sometimes the two lobes are connected by a band only, which is similar in structure to that behind the cava. No ducts ramify in the coats of the gall-bladder. It is probable that Ferrein mistook the absorbents of the gall-bladder for ducts, this anatomist, probably, having injected some of the former vessels, as I have frequently done, from the hepatic duct: or Ferrein may allude to ducts which occasionally ramify between the liver and gall-bladder, and di-

vide into interlobular branches, which enter the former, and which he may have removed with the latter, and mistaken for ducts ramifying upon it. No branches of the hepatic veins ramify in the coats of the gall-bladder; and the absence of these vessels sufficiently proves the non existence of ducts. The cystic veins are branches of the abdominal portal, and not of the hepatic portal or umbilical vein: they are therefore efferent, and not afferent, vessels, conveying blood from, and not to, the gall-bladder: it necessarily follows, that biliary ducts ramifying on the parietes of this receptacle would receive the materials of their secretion from arterial blood,—that of the cystic arteries. If in any case ducts should be found on the gall-bladder, I venture to assert, that branches of both the portal and hepatic veins will also be found; but the portal veins in such a case will be branches of the hepatic portal vein, will convey blood from the coats of the excreting ducts, and to the coats of the secreting ducts, and not from the gall-bladder. If ducts, arteries, and one set only of veins, terminating in either the portal or hepatic veins, should be found—and this is always the case, if Ferrein's assertion, that ducts ramify on the coats of the gall-bladder, be true—then would the bile of these ducts at least be secreted, beyond dispute, from arterial blood.

Branches of the hepatic artery and portal vein accompany the ligamentum teres; these veins convey blood to the hepatic portal vein, and must therefore be considered as separate branches of the abdominal portal system.

Of the Lobular Venous Plexuses.—The interlobular branches of the portal vein, surrounding the lobules on every side except at their bases, divide into branches, which, entering these bodies, form in each of them a plexus, the branches of which terminate in the intralobular hepatic situated in the centre of the lobule. This plexus, interposed between the interlobular portal veins and the intralobular hepatic vein, constitute the venous part of the lobule, and may be called the lobular venous plexus. Examined with a powerful microscope, the vessels constituting the plexus are seen converging from their origin at the circumference toward their termination at the centre of the lobule; they communicate with each other by smaller transverse branches, between which are seen minute circular, ovoid, or oblong spaces, occupied by portions of the lobular biliary plexus. (Fig. 7.) Examined with a less powerful microscope, the vessels of the plexus appear arranged in circles. The circular, ovoid, and oblong portions of the biliary plexus, seen between the branches

of the venous plexus, are the acini of Malpighi. Müller has delineated the converging vessels of the plexuses in the liver of the squirrel; but this anatomist did not ascertain whether they were branches of the portal vein or of the hepatic artery. The venous plexus of one lobule communicates with the plexuses of the surrounding lobules by means of the intervening interlobular branches of the vena porta; this vein thus forming one continuous plexus through the whole liver. The converging branches of each plexus unite at the centre of each lobule, and form an intralobular hepatic vein, this vein having no communication with the corresponding veins of the contiguous lobules, except through the medium of the intervening plexus and portal veins. No branches of the hepatic veins are found in any other part of the liver; occupying the centre alone of each lobule, their only office is to convey the blood from the lobular venous plexuses, and not from the arteries.

In consequence of its double venous circulation, the liver is naturally in a state of sanguineous congestion; hence arises the great difficulty of making successful injections of the human liver: the plexuses may, however, be frequently well, but seldom equally, injected, and always with greater success from the portal than from the hepatic vein, the latter, and those portions of the plexuses immediately surrounding its intralobular branches, generally containing whatever blood may remain in the liver after death. The plexuses may be always injected with facility from the portal or hepatic veins, and the injection will pass freely from one vein into the other without extravasation, if the liver has been previously deprived of all its blood by the ligature of the portal vein and hepatic artery in the living animal.

Anatomists have considered, that the free communications which exist between the two vessels obviate the difficulty which would otherwise arise in the circulation through the liver, from the want of power consequent on the presence of the two veins; and although the communications between these vessels appear, upon experiment, to be more free than those which exist between the hepatic artery and the portal vein, and between arteries and veins generally in other parts of the body, yet it appears that the arteries and veins in the spleen and kidney, and probably in all glands, communicate with equal freedom. The lobular venous plexus is best examined in the superficial lobules, but here again the human liver presents a difficulty, particularly in the adult, in consequence of the opacity of the proper capsule: the

liver of the cat, and that of the smaller animals generally, appear to have no cellular capsule, and are consequently more favourable for this purpose.

The venous plexus ramifies on the biliary plexus: the blood circulating through it is composed of the portal blood, and certainly of that portion of the arterial blood which, having nourished the excreting ducts and supplied them with mucus, and having circulated through the vasa vasorum of all the vessels, becomes venous, and is received into the branches of the portal vein, by which, with the portal blood, it is conveyed to the plexus; and from this mixed blood the bile is secreted.

The vessels of the plexus ramify on, or as Müller says, between, the secreting ducts; they are not continuous with the ducts, as was imagined by Ruysch.

[The engravings referred to in the preceding pages will be given, with the conclusion of the paper, in our next number.]

[To be continued.]

OBSERVATIONS ON THE NATURE AND ORIGIN OF THE DISEASE

CALLED

PLICA POLONICA.

BY GEO. WM. LEFEVRE, M.D.

Physician to the British Embassy, St. Petersburg.

[Concluded from page 337.]

It is evident, to me at least, that there is a disease in some parts of Poland which does not exist in other parts; although the moral and physical habits of the people are the same in both. This disease I divide into real and artificial: the former exists in the proportion, perhaps, of one-tenth to the latter. I shall first describe the artificial—the manner of producing it, and its final termination. During my residence in Poland, I had no opportunity of witnessing a plica pass through all its stages, from the beginning to the end; but I saw several, at various periods of their progress.

The artificial plica is fomented, as I have observed, with the idea of producing a critical discharge, which will relieve the system of some *preccant* matter, to make use of the old phraseology. This disease, when produced by artificial means, is confined to the head; and I know of no instance where means have been taken to form this in the hairs of

the scalp, that other parts of the body; have suffered naturally from the plica: nor have I ever heard of attempts having been made to produce this complaint in the axilla, or on the pubes. This may, in some measure, help our diagnosis between true and false plica: in the formation of the latter, nothing more is necessary than to allow the scurf and secretions of the scalp to accumulate. This is promoted by wrapping the head in flannel, which, keeping it warm, increases the natural secretions of the scalp. The hair, in the course of time, elongating, and not being combed straight, aided also by the twisting of the night-cap, or flannel, becomes plaited together in various forms and shapes, and the interstices fill up with the exudations which come from the scalp, and from the myriads of animals which breed there unmolested. We will not instance an example furnished by Kirby and Spence, where servants were employed all day in carrying them away from the head of their master by baskets-full at a time; but I have seen them numerous enough. In the course of time, this contact with the secretions, which are probably of a morbid nature (for this means of forming a plica becomes derivative to a body already diseased), destroys the bulb of the hairs, and the whole mass, which now resembles a bird's nest (and a dirty one, too), forms so much extraneous matter. If unmolested, however, and left for a sufficient time, it falls off finally in a mass, "pushed from its stool" by the young healthy hair which sprouts up underneath. It is seldom allowed to finish its career in this manner. The patient watches the arrival of the new hair, and, as it increases, he cuts off piecemeal the old plica; or as I have more frequently seen the operation performed, a lock of the old hair is inclosed between two pieces of wire, and these are tightened daily, till it drops off.

I saw this process employed by a Jew: the only case I met with among the Jews. A singular fact is observed with respect to the nails, when the young hairs begin to shoot, and which I witnessed in the same individual; for his was originally a case of true plica, but, as in most instances, was changed in its real and natural character by artificial means. The nail, in these cases, no longer grows from the root: it becomes of a horny nature, and opaque, and finally

shelves off, leaving a young nail underneath.

This, then, is the general way in which the plica takes its final departure, and woe to him who wishes to expedite the process too rapidly. Sudden death, blindness, palsy, apoplexy, deafness, idiotcy, are some of the ills which are said to follow invariably a sudden removal of the disease by excision.

In the history of this disease, as hitherto related, it is evident that there is nothing very extraordinary in its formation and progress—nothing to warrant the existence of a particular virus; nor, indeed, any morbid state in the hairs themselves.

If all the cases upon record are of the same nature as the foregoing, then, indeed, we may conclude, with Davidson and later French writers, that there is in reality no such disease as plica polonica.

If we are to believe the testimony of such as can have no interest in warping the evidence which nature presents, there is a disease of a different character, arising spontaneously, and not originally produced by artificial means, though too frequently changed in its appearance by the latter. It is that which occurs in the higher classes of society, and which attacks other parts of the body than merely the hairy scalp. Most wonderful cases are upon record of the extent to which this complaint proceeds.

The hair of the head is related by several to have been long enough to train upon the ground—to be three, four, and even six feet in length, and to extend laterally in proportion.

The beard is said, by Alibert, to have reached the same dimensions; and Dr. Corona knew a Polish hermit whose beard trained upon the ground when he lay in bed.

"Jean Hain rapporte l'observation d'une femme qui avoit les poils du pubis affectés d'une plique longue d'une aune et demie; il ajoute que la personne était obligée de la rouler autour de ses hanches, pour empêcher qu'elle ne traînat par terre."

These are what I imagine to be cases of real plica, and similar cases are rare in occurrence comparatively with the artificial plica already mentioned; still there are sufficient instances upon record to allow of the authentication of the disease. I could not, during a six months' residence in Cracow, find an opportunity of witnessing this affection in its early stages. All the cases which I saw, in

private families and in the public hospitals, were decidedly manufactured; but I knew those in high life, of all ages and of both sexes, who had suffered from the disease. The case of the Jew was a case of real plica, but it was only when the disease was far advanced that I saw it. I must consequently describe the appearance which the real plica assumes at its commencement from what others have told me, not being able to do so from personal observation.

We find in the descriptions which we read of it, a great variety of statements, as regards the changes in the structure of the hairs. Some speak of a glutinous matter exuding from the filament, if cut asunder; others have found blood issue from the divided ends, and the cutting of the hair itself is said to be productive of great pain. Others declare that, with all the assistance of the microscope, they could not discover any change in the structure of the hair itself, but merely an exudation from the scalp at the roots of the hair.

All this discrepancy of opinion arises from partial observations, from confounding the false with the real plica, from studying the affection at certain stages of its existence only upon different parts of the body. I shall quote the description given of this disease by a very popular writer, who has, nevertheless, in several particulars been misled by partial information.

"The individual hairs begin to swell at the roots, and to exude a fat slimy substance, frequently mixed with suppurated matter. Their growth is at the same time more rapid, and their sensibility greater, than in their healthy state; and notwithstanding the incredulity with which it was long received, it is now no longer doubtful, that where the disease has reached a high degree of malignity, not only whole masses of the hair, but even single hairs, will bleed if cut off, and that, too, throughout their whole length, as well as at the root."

We cannot coincide in the truth of every part of this quotation. It is true that the roots of the hair become extremely sensible; but the filament is not so itself, nor is pain produced by cutting it throughout its whole length. With respect to the bleeding from the ends of the divided filaments, I found so much contradiction in the evidence to be procured upon the subject, that I could not convince myself that such was the case.

It is more probable, I think, that the scalp becomes diseased and very sensible, and that blood issues from the roots of the hair when they are pulled out; but I do not think that the individual hairs ever become injected throughout their whole length.

The hair is not, as it was long supposed, an inorganic substance; it possesses vitality, although slightly comparatively with other parts of the body; and derangements of the general system may influence the hair individually. The degrees of vitality and sensibility are not the same in all textures at all times. Inflammation changes an almost insensible healthy, into an acutely sensible diseased membrane; so it may be with the hair, which, possessing little vitality or sensibility in a natural state, may acquire both under diseased influence.

In referring to the authors who have written upon the hair, we find some curious cases, in which its colour even has been changed by fevers, and even by passions and affections of the mind.

Rudlein relates the circumstance of a patient's hair becoming yellow, after a fit of the jaundice.

Dr. Tourron, of Thoulouse, instances the case of a woman, thirty-six years old, who was attacked with a brain fever, and whose hair and eye-brows got white during her convalescence, but returned to their original black colour when they were quite restored.

M. Alibert mentions the case of another woman, whose hair was fair, but after a severe illness and accouchement it became black.

The effects of fear and terror in changing the hair to white, has occurred in more than one instance in modern times. Such effects could not be produced upon inorganic matter; and we find that the centre of each hair is perforated by a fluid, which imparts to it vitality. If the hair be organized, and this seems placed beyond doubt, it may be subjected to the diseases of organized structures, and the roots of the hair may be penetrated by diseased fluids secreted from the scalp, and which eventually produce disease in the hair itself. It is probably the escape of some of this diseased secretion from the hair, when divided near its root, which has given rise to the opinion of its bleeding.

This applies, therefore, to that state of the system which is found to occur in

that species of plica which is formed originally by diseased secretion, and is not produced artificially. This affects all parts of the body where the hair abounds, whereas the artificial plica is confined to the head, where alone it has been fomented.

A minuter examination will discover the difference between the true and artificial plica, as cognizable in the structure of the hairy filaments. The bulbs of these are enlarged from the commencement in the true plica, and the disease affects them individually. The hairs become enlarged from the increased quantity of fluid injected into them, or from some change in the nature of their proper fluid, produced by disease. It is from this circumstance that the hair, if not meddled with, nor allowed to be compressed, so as to form a mesh, sticks out like a pole: hence the popular name *koltum*. If situated upon the head the disease is easily recognized from the false plica: the roots and bulbs of the hair are found diseased as they issue from the scalp itself; whereas in the bird's nest plica, the turban plica, the medusa plica, all of which are produced by art, there is a considerable length of sound hair between the scalp and the plica; and if a single hair be separated from the mass, it will be found in a healthy state.

The interlacing and matting of the hair are not necessary to characterize a true plica, but this is often produced by the same means as are used to form an artificial plica. Hence to a superficial observer both appear the same; hence the existence of the true plica has been called in doubt, because it is similar in appearance to the artificial plica; and hence truth and error become confounded in one common mass.

Let those who are still sceptical upon this point, and who do not believe in the existence of the true disease, answer this simple question. Have they ever known an artificial plica formed in the axilla, or on the pubes? What name do they then give to that disease which affects the hair upon these parts, in the manner which we have described?

In recapitulation, therefore, we must observe, that we do not believe the plica polonica to be an imaginary disease, resulting only from filth; neither do we believe it to be contagious, and capable of propagation by inoculation; but we believe that it is a secondary affection, a species of critical evacuation, which

becomes a source of irritation, and produces disease in the hairy filaments.

That the greatest proportion of what are called plicas are the result of art, is undeniable; and it is equally so, that the generality of observers, in passing through the country, have been satisfied with unravelling these false plicas, and have supposed that they have unravelled the whole mystery.

It remains to inquire into the causes of the real disease, in doing which, the manufacture of so many artificial ones will be easily accounted for. In endeavouring to discover the real cause of this malady, we shall refer to the works of an author who has thrown much light upon a very obscure subject, and has, like most original writers, incurred the charge of eccentricity and exaggeration: we refer to Dr. Macculloch's work on fevers and neuralgia, arising from the influence of Malaria. That many affections are, in their causes and characters, difficult to trace and distinguish, is the result of every man's practice. It is not *nosological disease* which is the most difficult to treat; there are a variety of uneasy affections and sensations which baffle us all in our practice: hence the tyro becomes astounded and humiliated at the very onset of his career, to find himself, with all his learning, unable to account for the cause of so common a complaint as the toothache. His Cullen's Nosology stands him in bad stead for a practical guide; he enters upon the wide manor, and finds but little legitimate game to exercise his skill upon; he is assailed by a multitude of complaints which he has neither read of in books, nor heard of in the lecture-room. It is not the tyro alone who has to struggle against these difficulties; it is, perhaps, the octogenarian, going down to his grave disgusted with the idea that a life has been devoted to a profession of which he feels that he knows so little.

Dr. Macculloch has endeavoured, in his work, to pour the oil and wine into his wounds, and to apprise him, even at the eleventh hour, that there is a balm in Gilead. As a sweeping clause, the Doctor considers "all fevers which are not produced by contagion, to be the result of malaria." He dwells at some length upon the direct and indirect effects of this poison upon the system, as it is evident in producing intermittent and remittent fevers, and as it is more obscure in its action, as producing a

great variety of anomalous sensations and complaints, all of which, however, may be reduced to a simple cause, and will be found to have a remittent fever for their basis, and malaria for their excitement.

From the general effects of malaria upon the system, producing remittents and intermittents with all their obscurities and anomalies, Dr. Macculloch proceeds to local affections, which he attributes to the same cause. These are extremely numerous, and comprise all those local pains and aches which occur in the body, and are inexplicable both to the patient and the practitioner. They come under the head of *tic douloureux* when they affect the more tangible nerves, or their obvious branches—as in the face, the arms, the fingers, knees, legs, toes, &c. There are other local affections, which, although not so easily traced to a direct nervous filament, are equally included in this list, because the expansion of a nerve upon a muscle is equally susceptible of this disease, which the Doctor denominates *rheumatic neuralgia*, intermittent in its character and produced by malaria.

It remains only to determine whether the *plica polonica* is not to be added to the number of these obscure affections.

The locality of this disorder offers every ground for regarding it as the offspring of malaria. It is found almost always in marshy situations, and on the banks of rivers. The more common effects of malaria are found most prevalent among the inhabitants of the marshy swamps where *plica* is endemic. I never met with so many cases of ague as during my stay in Poland, and this of a severe and fatal kind. Rheumatism is as prevalent as agues, and affects every part of the body, and becoming chronic in the limbs, renders them useless. It attacks the head most severely, and *tic douloureux* in the face is of frequent occurrence. Rheumatic ophthalmia and amaurosis, in a gouty diathesis, are of common occurrence. Mr. Russell, speaking of the *plica*, says, "it is generally preceded by violent headaches and tingling in the ears; it attacks the bones and joints, and even the nails of the fingers and toes, which split longitudinally. If so obstinate as to defy treatment, it ends in blindness, deafness, or in the most melancholy distortions of the limbs. The most extraordinary part of the disease is its action upon the hair."

In this last phrase, the author states

an opinion which has the more weight as it comes from an unprofessional man, unbiassed by any theories. The *plica* is here stated to be a general affection, the state of the hair a symptom only.

Paralytic affections are very frequent in the same unhealthy situations.

If all these constitutional symptoms, which are said to precede the formation of a *plica*, are, as Dr. Macculloch informs us, attributable to malaria, I do not see why the affection of the hair should be excluded from the list. The same poison which operates in producing an affection of the scalp may certainly influence the roots and bulbs of the hair. It is, indeed, singular, that he who discovers this protean cause of so many complaints where it is difficult for others to trace its influence, should not himself have discovered it here, where it is so much more ostensible.

If it be asked why malaria should produce this disease in one country and not in another, it may be replied, that many circumstances, at present inscrutable, influence the effects of this poison upon the system. Why should it attack the testicle in one, and the kidney in another? Why the great toe or the little finger? Why the supra-orbital nerve or the portio dura? Why produce a slight ague or a deadly remittent? Why a dysentery or a cholera morbus?

To such questions we can only oppose a set of unmeaning terms, as predisposition, endemic fomes, habits of body, difference of constitution, climatic influence, which answer the same purpose in medical language as capacity for caloric or latent heat, do in chemical; or as length without breadth does in mathematical definition.

We have as much right to conclude that there is some peculiarity in the climate or in the soil, or in the habits of an individual, which causes malaria to operate in producing *koltun* in one situation, as that it shall produce a rheumatic ophthalmia or a fever in another; for the effects of diseases in general are not so much to be studied in their own peculiar and specific characters, as in the various circumstances under which they operate.

It may be inferred, I think, from the preceding observations, that the custom of the people in promoting *plica* has arisen from the relief afforded to their pains and aches by the generation of a true *plica*. They have observed that when the hair became thickened, and as-

sumed an appearance of a stake, long and tapering towards the extremity, so the affection of the system which preceded this state began to disappear, and consequently whenever they are attacked with any severe rheumatic complaint in the head or limbs, or when their eyes become diseased, they immediately set about manufacturing an artificial plica. This produces a less speedy relief to their complaints than when a plica is the natural result of a critical discharge from the scalp, but it nevertheless produces a good effect from its slowly derivative action. The enveloping the head with flannel, and the other accessory means which time effects, keep the scalp in a state of fermentation.

From the whole, therefore, we conclude that the constitutional affections of the system are the produce of malaria, and that the local affections are generated indirectly by the same cause. The plica is therefore produced by a morbid secretion from the parts in which the hairs are imbedded, which penetrates the hairy filaments and produces disease; but this, which becomes the exciting cause of a local disease, is the critical termination of a constitutional malady. This natural process, which affords relief to the system, and becomes, in fact, the cure of painful affections, is imitated by the people so universally upon all occasions where they suffer from pains and aches, that the number of false plicas is in immense proportion greater than those produced by the efforts of nature in the process of critical discharges, and this accounts for the uncertainty and controversy which have so long existed regarding this complaint.

With respect to a primary affection of the hair occurring spontaneously, and not preceded by any general symptoms of morbid action in the system, I must have my doubts. I made many inquiries of the medical men with whom I associated, and I could never find any one who had seen the plica as an original affection commencing in the hair itself. I see no reason, however, to deny the possibility of such an occurrence. I shall not speak of the means employed to cure this affection: my sole object has been to endeavour to explain the causes of so much contradiction in the evidence stated regarding the nature of this singular complaint.

September 1834.

M. BRESCHET'S OPERATION FOR THE RADICAL CURE OF VARICOCELE.

To the Editor of the Medical Gazette.

SIR,

It has hitherto been confessed, that, amongst the affections for which surgery possesses no radical cure, varicocele holds a foremost place; for in the present improved, and, if I may so speak, refined state of surgical practice, it would be needless to combat the various proposals of castration, excision of the dilated vessels, &c. &c.; their ephemeral reputation sufficiently proves their inexpediency. Nor can I view with much confidence the plan adopted by M. Amussat—viz. ligature of the spermatic and scrotal arteries; although that mode of treatment be said, in at least one instance on record, to have been attended with a favourable result.

The honour of increasing the domain of curative surgery, by a radical treatment of varicocele, appears to have been reserved for M. Breschet. This distinguished surgeon has, in fact, devised a plan, simple as it is ingenious, by which the most inveterate scrotal and spermatic varices are completely and expeditiously removable. I shall proceed to lay before your readers a brief account of this plan, accompanied with a case in which it was employed. I make choice of the first case in which M. Breschet operated, in order that the attendant difficulties of a first trial may not be concealed, and, at the same time, that the timid may not imagine them greater than they really were.

The patient was a servant, æt. 29, robust, and of strong constitution, who, so early as the age of 15, had perceived a difference in the conformation of the testicles. Some years afterwards, a tumor and varicose dilatation of the left scrotal veins became evident. The patient was frequently obliged to give up his ordinary work. He was admitted into the Hôtel Dieu, May 27, 1833.

The diagnosis of the affection was easily established; the usual symptoms of spermatic and scrotal varicocele existed in a very marked manner. Many of the dilated veins of the scrotum equalled in size the auricular finger; and a fasciculus of vessels, united so as to form

a considerable mass, originated at the cauda of the epididymis, from which point they followed the course of the cord to the external abdominal ring. The vas deferens was recognized by the characters which are peculiar to it.

The usual palliative treatment was prescribed, and its use continued during a month. The veins of the cord and scrotum, during that period, became slightly diminished in size, but the increase of volume which followed the erect position clearly indicated that the treatment had been, indeed, but palliative. Pressingly urged by the patient, M. Breschet thought of putting into execution a mode of treatment for a radical cure, the idea of which he had previously conceived. The principle upon which it was based was the obliteration of the affected vein *by compression*. The compression was at first produced by small iron pincers, the pressure of which was always equal, and resulted from the simple elasticity of the branches of the instrument. But the difficulty of using these pincers, their occasionally too great pressure, and the impossibility of padding their metallic surfaces, induced M. Breschet to use in their stead others so formed as to permit the part destined to come in contact with the scrotum to be covered with soft linen, or leather, and the pressure to be graduated at will, by means of screws.

The instruments were at first applied on the veins of the scrotum, at the extremity of two of the most voluminous of them; care being taken to leave no considerable anastomosis between the two points compressed. Their presence determined slight local pain, and the trifling inflammation which followed was combatted by emollients, resolutive, and repose. On a second application, the pain was much less considerable; the graduated compression caused a thinning of the skin, and, bringing the two opposed portions of that membrane into contact, produced a dry eschar, solid, thin, and transparent, resembling parched paper. Its detachment was followed by an ulceration of much less extent, and less painful, than in the former instance. These ulcers were perfectly cicatrized in a few days; they produced no hemorrhage. The vein remained full of clotted blood; this blood was gradually absorbed; no inflammation took place; and subse-

quently all traces of the existence of the vessel had disappeared. The different veins of the scrotum were successively treated in the same manner.

This success was, however, incomplete. The spermatic veins still remained. The application of the instrument to them was not so easily effected. They were surrounded by a thick skin containing fat, and the vas deferens was in their immediate vicinity. The small size of the nerves and arteries prevented their being drawn aside. The accidents to be apprehended were pain, violent inflammation, formation of a deep eschar, and denudation of the cord. For this new application the instruments were modified, so as to offer a larger surface to the part affected, and to present a curve which should prevent the pressure of the fold of the skin. The vas deferens was excluded. The pain on the application was considerable, but removed by local means. The instruments were kept on seven days; one placed as near as possible to the external ring, the other towards the inferior part of the cord. They determined an inflammatory swelling of the parts comprised between the two pincers, and produced a superficial eschar of the part on which they immediately acted, combined with an adhesion of the two opposed cutaneous surfaces. The consequent ulcerations were cicatrized in less than fifteen days; before which time the cord had lost its knotty feel. There, however, still existed, at the cauda of the epididymis, a mass of vessels extending as far as the place of the last compression. Two other pincers were applied; one immediately before the testis, which was drawn backwards, the other two inches higher up. They were kept on the same number of days as the preceding, and followed by some pain, inflammatory swelling, and eschars of the integuments.

It deserves remark, that the inflammatory symptoms, after this last operation, were more violent than before, and less promptly removed. The instrument placed above the testicle produced a perforation of the skin, and a solution of continuity resembling that produced by a seton. The inflammation and swelling were considerable; an abundant oozing of a sero-purulent matter existed during fifteen days, from the ulcer. These accidents were got under by

emollient cataplasms and repose, and at the same time the varicose mass which had existed at the bottom of the scrotum was converted into a small tumor, in which no trace of vessels was discoverable. The disappearance of the swelling soon permitted an examination of the testicle, which had been long lost amid the vast fasciculi of vessels. Its nutrition was found to be unimpaired, and its volume equal to that of the opposite side. The cure was perfect at the end of November.

The length of time occupied in the cure of this case, is by no means to be attributed to the method employed in its attainment, but to the various difficulties encountered in devising and having made the instruments employed, and to the caution necessary in the first trial of an operation of which the ultimate results could not, *à priori*, be fixed with any degree of certainty. M. Breschet has since operated in numerous cases, both in public and private practice, with perfect success, and obtained in a much less time. I have myself seen two cases treated by him at the Hôtel Dieu, in which the cure was perfect in from four to five weeks.

It is exceedingly important that the compression be more than sufficient to induce an adhesive inflammation, with occasionally slight suppuration, of the coats of the veins; such an effect would not only be insufficient, but might be injurious, from the propagation of the inflammation along those coats, or from the purulent infection of the blood. The pressure should be forcible enough to destroy the life of the part, but in a gradual manner. The mortification is confined to the part immediately acted on.

I should have wished to subjoin a sketch of the instrument, but unfortunately could not procure one as a copy.

I have the honour to be, sir,

Very respectfully yours,

WALTER H. WALSHE.

November 26, 1834.

BIRTH OF A DOUBLE FŒTUS.

To the Editor of the Medical Gazette.

SIR,

I FORWARD to you a singular case of the birth of a double fœtus, which has lately occurred in my district, should

you deem it worthy of notice in your excellent journal. I am aware that cases similar to the following are recorded by authors, but happily to be met with rarely in practice.—I remain, sir,

Your obedient servant,

S. W. KIDGELL.

Pangbourn, Berks,
December 3, 1834.

On the 23d of November last, the husband of a female pauper called on me with a request that I would immediately visit his wife, who had suffered many hours under violent labour pains, and was attended by a midwife. She resided at a small village about four miles distant. The woman was 38 years of age, well formed, the mother of seven children, and had always enjoyed the most perfect health. In my absence, my assistant, (Mr. Webb), visited the case, and when entering the house was informed by the midwife in attendance that the uterus had acted very powerfully during the night; that the membranes had ruptured some hours; and that the delivery was interrupted by some unusual presentation. On examination, the os uteri was found to be fully dilated, the womb contracting very forcibly, and almost alarmingly. The head of one fœtus had partially protruded naturally, and the arm of a second was discovered to have presented. Notwithstanding the protrusion of the head, and the very forcible contractions of the uterus, for some time no progress was made; therefore the hand was gradually, but with difficulty, introduced into the vagina, with a view of ascertaining the impediment to delivery, when it appeared that some monstrous formation had taken place. By gentle and gradual traction, however, the breech and lower extremities were brought down, speedily after which, without manual interference, the second fœtus was expelled, connected to its twin by an inseparable union from the lower margin of the sternum to the pubes. They were females; still born; of full size and weight. Their heads were of ordinary shape; presenting nothing remarkable, except their entire resemblance to each other; and their extremities were perfectly formed. The funis and placenta were single in every respect; the former not of unusual thickness, and about twenty inches in length, terminating in the umbilicus at the central and inferior part of their junction.

I should have felt more satisfied had I been permitted to have inspected their viscera, whereby my ease would have been rendered more complete, but to that measure, I regret to say, the parents decidedly objected.

A slight degree of hæmorrhage followed the expulsion of the placenta, which was checked without difficulty; no untoward symptom followed, and the poor woman is now fast recovering.

THE PRESENT CRISIS WITH REFERENCE
TO
MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

ALLOW me again, though after a long silence, to address you on Medical Reform; the passing day is, it seems to me, of great interest. The recent transactions at Brighton are not interesting to nations only, or to statesmen; their operation on the macrocosm of European politics will doubtless be pregnant with mighty consequences, begetting feelings and impulses in quarters and directions in which society has been either sluggish, or too slowly advancing, in this and other countries. But in the little world of medical politics their influence will likewise be felt, and will be, as I trust, efficiently, though indirectly, operative, through the whole frame and constitution of our profession.

What was the position of the legalized medical authorities before the dismissal of the Whigs? This; that by inquiries entered into by a Parliamentary Committee, granted contrary to their wishes, and animated, they feared, by a spirit hostile to their vested interests, and to a considerable extent by the evidence of their own members, and even partisans, they have been proved incapable of adequately protecting the public or the profession; the former from ignorance or imposture, the latter from unlicensed competition; so that their diplomas or licenses are, practically speaking, proof unequivocal of little more than the expenditure of certain sums of time and money in the purchase of titular or parchment honours and privileges; and that, consequently, extensive organic and other

changes, demanded by the spirit of the times and the wants of society, and hitherto denied to be just or necessary, and obstinately refused by the institutions complained of, were at length about to be undertaken by the paramount authority of parliament. The occurrence, therefore, so much dreaded, and so often and earnestly deprecated, viz. that of a reform *ab extra*, appeared impending, and awaiting only the lapse of a few months for its completion; and the decayed or defective institutions lay humiliated and discouraged, unwilling to accept, yet powerless to prevent, the expected innovations.

But now that the reform coach, to use H. B.'s phrase, is in good earnest in danger of an upset, and drivers and guards, and probably passengers also, all about to be spilt together, and the Whigs out of place, and parliament apparently (see Spectator, November 29th) on the eve of dissolution, what is the position of the medical governing bodies? Why, assuming a dissolution, it is, I should say, greatly altered for the better; for the dissolution will, legally speaking, convert Mr. Warburton's documents, one and all, into so much waste paper, value at most twopence per pound; and the Colleges will be re-established *in statu quo ante bellum*, precisely as before the war of witnesses, commenced and conducted with such signal perseverance, and, as I believe, purely public-spirited views, by the hon. member for Bridport. And with all the power of reform they ever had, they now have weighty reasons, not before so correctly estimated, for no longer subjecting themselves to the charge of a denial of justice, or of a bigoted attachment to withered and sapless distinctions; and are, I speak of the members individually, animated more thoroughly at the present moment than at any former period, with a disposition to meet all reasonable demands, and remove all proved abuses.

Thus Mr. Warburton's inquiries, however insignificant in a parliamentary sense after a dissolution, will yet not have been without important, and even precious fruits. Not only have they tended to soften the opposition to innovation on the part of the parties in possession of place and privilege, by proving incontrovertibly that defects and grievances do exist, sufficient to justify to some extent dis-

satisfaction and complaint, but they have, I conceive, likewise beneficially operated in another way, viz. by diminishing the bitterness of crimination and assault on the part of the excluded, by relieving them from the charge of groundless and petulant discontent, and releasing them from all anxiety as to the ultimate result, by unequivocally enlisting in the cause of medical reform the love of justice and sound sense of the general public; so that Mr. Warburton's labours have, in point of fact, greatly narrowed the debateable tract, by defining it; have lowered the temperature of feeling of the combatants; and brought each more nearly to that calmer tone and temper which is an indispensable preliminary to an amicable settlement of disputed claims.

Now assuming the neutralization of Mr. Warburton's labours, at least in a legal sense, by a dissolution, and assuming that the evidence procured by that able gentleman would have enabled him to make out an irresistible case for reform, let us inquire what is the policy pointed out, alike by good sense and good feeling, to the Colleges of Medicine of Pall-Mall East, Lincoln's-Inn-Fields, and Blackfriars. It is plainly, I think, this—viz. to make, as soon as may be, all reasonable *concessions* to their respective subject bodies; to make both eligibility and the elective franchise more nearly, if not wholly, co-extensive with membership; to abridge or abolish all privileges hitherto attaching, directly or indirectly, to accidents of birth, education, opinion, &c. &c.; to abandon the practice of stigmatizing, in any way, particular branches of the healing art, even the least of whose subdivisions is respectable if practised by men of character; to raise the standard of education, not, however, by multiplying certificates, which, whatever else they prove, are quite incapable of proving the main point—viz. the application of the student's mind to his appropriate studies, and the attainment of the requisite amount of real knowledge and available acquaintance with disease, its signs, causes, and remedies; but by strict examination, catechetical and practical, of the aspirant to professional honours and emoluments. The adoption of measures founded on the views and principles just glanced at, is plainly, I think, the policy most becoming the

wisdom and patriotism of the Colleges and now that they have had their cards, as I suppose, restored to them, and an opportunity afforded of retrieving past errors, and of recovering alienated attachment and winning golden opinions, I am sanguine in my expectations that the sound judgment and kindly feeling which, as I know, characterize many leading members of each College, will not fail to shew themselves, and that their possessors will not neglect to avail themselves of the sunny hour, and by timely and graceful concessions do honour to themselves, and to the state some service.

The "GAZETTE" is supposed, and I believe with good reason, to possess much more influence with the medical authorities than any of its contemporaries; and I beg leave to propose to the Editor the query whether he might not materially advance the good cause, by devoting a few of his eloquent leaders to the subject of *spontaneous* reform. To his superior literary ability, and ample means of elucidation, I would gladly consign the task of stimulating zeal, guiding inquiry, pointing out the best means, and generally aiding those in office and authority in their endeavours to enlarge the basis and consolidate the disunited masses of the professional edifice. Now that for the second time they seem to have the game in their own hands, I cannot believe that the many eminent and influential gentlemen who declared before the Committee that reform was, to a considerable extent, safe, just, and desirable, will go back from their own statements, and, by allowing the present opportunity of *spontaneous amendment* to pass by, expose the dignified bodies to which they belong to another such badgering as they lately experienced. Justice, self-love, published professions, all conspire in calling on them for exertion. Difficulties there are none of importance, saving such as always beset indolence and timidity, however favourable the occasion or righteous the cause. The sluggard's cry and the coward's ever is, "There is a lion in the way."

Your obedient servant,

CIVIS MEDICUS.

London, December 1, 1834.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à alréger.”—D'ALEMBERT.

Outlines of a New System of Philosophy; being a View of the System of Sciential Medicine, or Medicine (and all Human Knowledge) as proveable as Geometry. BY THOMAS EDEN, Member of the Royal College of Surgeons.

WE have all heard of the sailor, who, being mightily pleased with the panorama of Captain Ross's expedition, said to his neighbour, “You call it *beautiful*, do you? I call it *philosophy*, by G—!” Mr. Eden puts us in mind of that sailor; he calls his book “philosophy,” but we fear with not half so good reason as the honest tar did the picture. As a specimen of the *philosophical* spirit in which our author writes, we extract the following:—

“It is the blind, fantastical, ignorant, and idiotic cant of the age; that diffidence and modesty are the inseparable attendants on, the characteristics of, true wisdom; that ‘a little learning is a dangerous thing;’ that ‘shallow draughts’ of truth ‘intoxicate the brain;’ ‘drink deep or taste not,’ are the first precepts of teachers, the great lesson of the moralists, the measured tattle of the poets, and the revered doctrines of all those who never ‘tasted’ a ‘shallow draught’ of real learning—who do not know what wisdom is, who never drank the living waters of the well of truth. The inculcation of such doctrines, together with the precept that ‘it is your duty to bow respectfully to all those who have obtained the respect of others,’ is the curse which every father throws upon his children—the well-adapted contrivance by which every pupil is kept a *ligger fool* than his teacher; it teaches diffidence—takes away all manly dependence on self—deprives, at once, the whole human race of all individuality, making every man a drivelling non-entity; the evasive ‘we’ I so constantly meet with, leaving to mankind no one *advancer*; not a single defender of the truth; but making every child of Adam a time-serving worshipper of any many-headed fool that looks frightful.....The concoction and the diffusion of these doctrines are the crafty

doings of the devil—the master-work of Satan, by which he, under the semblance of the amiable, cozens man to abandon reason—to forsake the guide which his Creator gave him when he withdrew himself.”

But the reader may ask, what is all this *system* about? and what is *sciential* medicine? We can only answer, that the latter appears to be an epithet of the author's invention, to distinguish *his* medicine from all other kinds—those being “*acephalous*,” or “born without brains,” which are not *sciential*. Let us hear himself:—

“When searching for a difference more *audible* than between ‘*sciential*’ and ‘*scientific*,’ the total inability of your science to reason, to decide, or to prove, offers me, and justifies my taking, the word ‘*acephalous*.’ That science of medicine, then, which is now resident in the heads of the heads of the profession, I (in contra-distinction to ‘*sciential*’) call ‘*acephalous* medicine,’ for it has no reason, it has no brains in it.”

As to the *system*, we must candidly confess it is too deep for us and our powers of penetration. We have spent some time upon it, endeavouring to catch a glimpse of scientific meaning any where about it, but have utterly failed. We were certainly fools for our pains: why did we not stop short when we came to the following definition?

“A science, or a portion of knowledge, or a truth, of the individual, or of the few, or of the many, or of the multitude, is of, or belonging to, science, knowledge, truth.”

We print the sentence (?) *literatim et punctatim*, as it is in the original; and we apprise the reader that beauties of the same sort may be found *passim* throughout the volume.

By the way, we observe a note, in which it is said—

“If any professor who wishes his authority to be put against *sciential* medicine, will send his name to me, I will be answerable that the public have the benefit of it; but, N.B. he must pay the postage, for there is no man in medicine whose mere authority is worth twopence.”

Now we have as little inclination to squander twopence in this matter as Mr. Eden, still less to take the trouble of sending him our name; but we beg, at the same time, in the most unqualified

manner, to protest against his "*scientifical* medicine," and to describe his book as one of the most stupid, impertinent, and grossly ill-written productions, that we ever remember to have fallen into our hands.

Traité d'Anatomie Descriptive, rédigé d'après l'ordre adopté à la Faculté de Paris. Par HIPPOLYTE CLOQUET. *Edition Belge, augmentée de Notes, extraites des ouvrages de Soemmering, Meckel, &c.; d'un Traité des Preparations Anatomiques; et de l'Anatomie des Regions, d'après Blandin. Avec un Atlas de 15 Planches in folio.* Dulan.

This work is now completed, and forms a handsome octavo volume, accompanied by fifteen plates, in which all the chief objects in anatomy are well represented. Space is admirably economised throughout; and when we consider the additions made to the original, which are both select and valuable, the atlas included, we cannot help recommending this as the best, at the same time that it is by far the cheapest, text-book for anatomical students who are familiar with the French language.

MEDICAL GAZETTE.

Saturday, December 13, 1834.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

PRESENT POLICY OF THE COLLEGES.

WHAT OUGHT IT TO BE?

AN interesting and important question just now arises, regarding the actual state and prospects of medical reform. In the event of a dissolution of parliament, which, we suppose we may say, is now certain, abundant scope is given for speculations of all sorts, relative to the effect of that occurrence on what has already been done, and on the probable fate of this among other objects of reform to be agitated under the auspices of the new ministry. The evidence, not-

withstanding its "hair-breadth 'scape" from flood and fire, by the instrumentality of Mr. Dermott—who, by the way, ought to have been presented ere this with some civic memorial for his invaluable services—and notwithstanding the precious attentions and fostering care bestowed upon it by certain needy speculators, who think it worthy of being committed to posterity in the shape of sixpenny pamphlets—may still go the way of all waste paper. This intelligence, we dare say, will be very afflicting to some parties; but we, who have all along contemplated the matter dispassionately, have no great regrets about it. It seemed to us that Mr. Warburton—the only member who could be got to take any trouble in the affair—gave himself a great deal of unnecessary labour, for no earthly purpose that we could understand, except to afford to all who chose to avail themselves of it, the opportunity of grumbling *ad libitum*, and of acquainting the nation with what they conceived to be the proper objects of reform. Months after months have thus been wasted—the public money squandered—and in the end a mass of manuscript and printed documents collected, which it would require the best efforts of some "heaven-born minister," in addition to the honourable member for Bridport, to digest, and reduce to a manageable compass. There was much valuable material among it, we admit; but it was wofully disfigured and obscured by the superfluity of trash with which it was encumbered: the weeds choked up the flowers—the tares encroached upon the more wholesome grain. One thing, however, has been certainly gained by the transaction—the feeling of the necessity for a *movement* has been inculcated: to stand or sit still, as the corporations have hitherto done, even in spite of the better judgment of their individual members, is now no longer possible; the

impetus has been given, and "*marche ! marche !*" sounded in their ears, in a tone scarcely to be disobeyed.

But let what will be the next proceeding on the part of the legislature, an interval of delay must take place, in which to be idle, on the part of the Colleges, were highly criminal. That interval may be turned to the best account. It is a season in which much that ought to be done may be done with no mean grace; and in which much that ought not to be done may be effectually prevented. But our valued correspondent CIVIS MEDICUS has, we perceive, anticipated us on this head. Bold as the measures were which were advocated by him not very long since, and energetically as he would have them put in execution, he can clearly see in the present turn of affairs the opportunity which offers itself for effecting changes far more temperate and beneficial—for making far more "graceful concessions"—than could have been well proposed under the late arrangements. For the nature of those changes and concessions, we would refer the reader to the letter of our correspondent, in a preceding page.

The friends of misrule—the advocates of destructive alterations in the things that be—will no doubt lift their voices on seeing any preparations for "setting houses in order"—for adopting, in fact, the very measures which they themselves pretend to desire. But the babble of the factions should only provoke contempt. We trust that no clamour from such a quarter will have any influence in retarding the work that should immediately be begun. There is at present no compulsion—no force operating from without, save that of public opinion; and in yielding to that, which, by the way, is very far short of the opinion of the violent few, there need be no sacrifice of honourable principle, nor of grade. It is never too late to take up the prac-

tice of what is right, and those who resolve to fall into the proper path, may safely do so without risking any character except that of consistency, or rather of obstinacy, *in error*. Reform, besides, is the order, the fashionable virtue, of the day; from the peer—nay, the premier—to the peasant, in some shape or other, it is the test or the watchword of patriotism. It would be a strange anomaly indeed, if, in such a state of things, a couple of chartered bodies, hitherto held in honour, as the source of much distinction in the profession—with the means, too, of ample and efficacious change for the better within their grasp—should alone sit still in the general movement. Will it be wonderful, if such should unfortunately be the case, that neither regard nor consideration should attach to parties conducting themselves so indolently,—if not vexatiously?—that when the time comes (as come it must) for material alterations in those bodies, suited to the circumstances of the period, no respect will be paid to the suggestions of the parties, but that they will be met with that cold scorn which they will have so richly merited?

ALL PRIME MINISTERS "ONE FACULTY" MEN.

WHEN Lord Grey was prime minister, the Editor of the *Lancet* told us that he was the fittest statesman in the world to carry through the great cause of medical reform. So fully was our contemporary convinced of this, that he was indignant at any surmise of the contrary; oracularly observing, "not one word of caution from the press is required by Earl Grey."

When Lord Melbourne succeeded, we were informed that the profession "had reason to rejoice," because he was even more fit than the noble Earl who preceded him, and "displayed exalted

firmness in prosecuting an inquiry into medical abuses."

The Duke of Wellington was next called to his councils by the Sovereign; and when it was supposed that *he* would be prime minister, we were assured that he was one "the excellence of whose tactics in civil government have been as generally admitted as has been the brilliancy of his genius in war;" that some hold him to be "more than a moderate amender of acknowledged abuses;" and, in short, that "there is no ground for believing that the Duke of Wellington will be less desirous of removing medical abuses than was the noble Viscount."

But now Sir Robert Peel is premier; and this, too, has been provided for. "Where?" asks our consistent and honest contemporary, "where was the honourable Baronet when the motion of Mr. Warburton was brought forward? He was present, assented to the proposition, and was immediately appointed a member of the medical committee; and of that committee the honourable Baronet is still a member." True—very true; but then there is one little circumstance omitted in the narrative; namely, that Sir Robert went to the committee some days after the sittings had commenced; that he objected to the manner in which they were conducted; that his views not being acceded to, he left the room, *and never entered it again*—a most potent indication, certainly, of his favour for the "one faculty" system.

Thus we have the satisfaction of knowing that, as regards medical reform, we are in a most satisfactory state: Lord Grey was good—Lord Melbourne better—the Duke of Wellington best—and Sir Robert Peel is "*most best*"—a very radical in medical politics. There is more in all this than is dreamt of in your philosophy, if we could but find it out; but till the true cause be discovered, and till Wakley's surreptitious edition

of the parliamentary evidence cease to fall still born from the press, we advise him at once boldly to adopt for its motto—

"And oh! in Downing-Street should Old Nick
revel
 England's prime minister—then bless the d—l."

ANATOMY ACT—INTERFERENCE WITH VESTRIES.

ONE of the greatest difficulties in the way of any satisfactory plan for the distribution of subjects for dissection, is the jealousy with which the teachers look upon each other. Thus, whatever seems likely to benefit one is opposed by another on this very ground; and we have heard of instances in which threats have been held out, *by medical men*, of pasting placards in the vicinity of workhouses, for the purpose of creating a tumult among the poor, rather than suffer a rival to gain his point. Until the parties concerned can come to a better understanding, and cease in their efforts merely to oppose each other, it is vain to hope for any change capable of affording general satisfaction.

Of the public displays of professions and acts apparently irreconcilable to each other, we must say that by Professor Quain is the most striking. This gentleman has written two long letters against the interference of the schools with the Boards of particular parishes in which they may have interest; and yet, in the second epistle, containing what he himself calls an "essay upon exertion," he (probably through inadvertency) admits that a recent and successful "exertion" has been made by himself to retain exclusive possession of St. Andrew's. The bodies from the parish in question have hitherto been exclusively given to the London *University*. We knew that an attempt had been made very lately to have other schools admitted to a share in the distri-

bution, and we thought that this application had succeeded, and that Dr. Quain, however reluctantly, was nevertheless a *bonâ fide* practical supporter of the non-intervention system. But in this we were mistaken; for we have since learnt that he not only opposed, but opposed with success, the appropriation of bodies from the parish of St. Andrew's to any school except that of Gower-Street. He speaks very bitterly of the attempt to effect a distribution, and then adds—"we were not, however, the persons to be tripped up so readily, even though taken unawares—we bestirred ourselves accordingly;" and then he emphatically adds, that the vote in his favour "remains undisturbed." Thus it would appear, that while he writes in the *Lancet* against teachers interfering with the parish authorities, so as to prevent a general distribution of the bodies, his practical comment on the doctrine is so to "bestir" himself as to induce the parties in question to stultify his own principle. We would not willingly do Dr. Quain an injustice, but we cannot see any other light than the preceding in which, upon the shewing of his own letters, this manifest inconsistency can be viewed.

We cannot, however, exactly understand why individual lecturers should be so anxious to obtain, and others to prevent them from obtaining, the supply from particular parishes, because, according to the present arrangement, it does not appear that they receive such bodies *in addition* to their share in the general distribution. The advantage must therefore be very trifling, unless any of the teachers so circumstanced neglect to make the proper returns, and thus appear to have had fewer bodies than is really the case. But this would be attended with such a heavy penalty, if discovered, while to avoid discovery would be so difficult, that (even setting aside all restraint from

feelings of honour), we can scarcely take it into our estimate as a possible contingency. Finding that the returns of the Inspector were open to examination, we have availed ourselves of the opportunity afforded us, and perceive that the numbers in some of the principal schools, up to last Saturday, were as follow:—Bartholomew's, 20; Guy's, 18; Webb-Street, 18; University, 18. It does not, therefore, appear to us, that there is any evidence whatever of Dr. Somerville having shewn a preference for any particular school*.

SUPERIORITY OF SMALL HOSPITALS.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH I had been told that the learned Professor of Physic, at the London University, had, by the aid of "the schoolmaster," arrived at the conclusion (since his resignation of St. Thomas's Hospital, where there are but 500 patients) that it is only in a small hospital, containing from forty to eighty beds, that the student can hope to attain any real knowledge of his profession, and that he had, in fact, stated this to his class, in his introductory clinical lecture, still my mind was too obtuse at first to believe that the deduction necessarily followed from the premises. I learn, however, that his excellent and equally disinterested colleague, the Professor of Materia Medica, has arrived at a similar conclusion, which he also has taken occasion to manifest to his class. I feel, therefore, that I should be wanting in duty if I did not urge on you the propriety, nay, the necessity, of impressing on the public generally a fact so new and so important. As the London University Hospital has certainly the advantage of being the smallest of the small among the hospitals of this metropolis, so is it, of consequence, the best adapted for teaching the treatment of disease. In the firm hope and

* In our leading article upon this subject last week, p. 344. col. 2, line 35, for *not read but*: the erratum is important, as it affects the sense.

belief that quackery of every description will never cease to flourish in this world generally, and in this town in particular, I am, sir,

Your humble servant,

A CONVERT TO DISINTERESTED OPINION.

December 6, 1834.

[If our correspondent will turn to vol. ix. p. 98, of this journal, he will find that the learned professor last alluded to devotes three columns of our smallest type to the elucidation of an opposite doctrine. He then lectured at a *Dispensary*, and said, "I am most anxious, indeed, to clear from your minds, gentlemen, the prejudices which have been so assiduously attempted to be impressed upon the student, against the utility of DISPENSARY practice." And again: "If you suppose that the results which you witness in the HOSPITAL are to follow the administration of the same medicines prescribed for similar disease in private practice, *you will soon find yourselves woefully mistaken!*" This may seem a riddle, when taken along with the more recent declaration in favour of any hospital small enough to afford a sufficiently limited field of observation; but the reading of it, nevertheless, lies in few words—the *Valetudinarium* was not then begun.—ED. GAZ.]

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

VI.—On Diseases of Joints.

I. *Of the Diseases of Synarthroses.*—Joints are of two kinds. In one there is no discontinuity; the bones which enter into the joint are united by an intervening layer of fibro-cartilage, and the articulation is strengthened externally by ligamentous bands, which stretch from bone to bone across the uniting medium. Joints of this kind, or *synarthroses*, exist between the bodies of the vertebrae, and between the pelvic bones; their pathology will form the subject of the present observations.

It will be best to consider, *in limine*, the habitudes under disease of the separate tissues which concur in forming these

joints. The tissues are three: bone, fibro-cartilage, ligament.

1st, The kind of bone, which enters into the composition of *synarthroses*, with a thin external crust, and a close and strong cancellous structure, has great vascularity and vitality.

a, It unites readily when broken.

b, It is liable to atrophy, in the two forms of rachitis and mollities ossium.

c, It is readily absorbed through pressure made by a growing tumor of the adjacent soft parts.

d, It is susceptible of inflammation. When inflamed, it rarely becomes more hard and solid, which is so frequent an occurrence in the cylindrical bones. It rarely becomes the seat of abscess. It frequently becomes softened, from absorption of its earthy matter, when it presents one of two appearances—either the internal periosteum highly vascular, and the cancelli filled with brownish gelatinous fluid—or with a less degree of vascularity, the cancelli filled with yellow curdy matter. Either of these states is eventually followed by caries, or ulceration; which ordinarily commences on a surface of the diseased bone, not in its interior, and is liable, but not likely, to be attended with partial necrosis.

2d, The fibro-cartilages in the *synarthroses* are generally not homogeneous; or there is every variety among them, from the sacro-iliac joint, in which the medium of union is nearly uniform, a layer of elastic substance, between cartilage and yellow ligament in structure,—and the pubic symphondrosis, where the exterior layers are more dense and fibrous than the central part,—to the fibro-cartilages between the bodies of the vertebrae, of which the exterior part, consisting of strong, white, silvery fibres, approaches to common ligament, while the interior part, a tissue *sui generis*, is of a soft and almost pulpy consistence, yet gliding, without any abruptness of transition, into the texture of the outer and ligament-like portion.

a, Fibro-cartilage, when torn, is susceptible of reparation. In fracture of a vertebra, the adjacent fibro-cartilage is generally ruptured; if the patient lives, it unites just as bone unites. The texture of the cartilage of a rib is perhaps too dissimilar to that of intervertebral substance, to be used in illustrating the properties of the latter; but I made some experiments upon the union of the costal cartilages, which I may take the present opportunity of mentioning. The cartilage of a rib was divided in several animals, which were killed at different periods afterwards. I found the initiatory stages of reparation which

had been set on foot to be exactly similar to those in bone. The cellular membrane surrounding the divided part was first consolidated into a firm capsule, which contained the cut ends of the cartilage. This consolidation was produced by the infiltration of lymph; an exudation of the same substance formed a medium of direct union between the ends of the divided cartilage. The reparatory capsule gradually became converted into a texture resembling cartilage. As, in the reparation of bone, the callus changes into cartilage, and then ossifies, subsequently to which direct union of the broken ends by bone takes place, so, in the restoration of a costal cartilage, the exterior thickening becomes cartilaginous, while the direct union of the divided ends is still by lymph alone. Mr. Stanley has two preparations of cartilages of the ribs in this stage of the process of union.

b, Fibro cartilages are susceptible of absorption upon pressure being made upon them by the growth of tumors, but in a much less degree than bone. Accordingly, in the growth of an aneurism of the descending aorta, the intervertebral fibro-cartilages are found to be absorbed superficially only, while the bodies of the vertebrae between them are deeply excavated and eaten away.

c, The intervertebral fibro-cartilages probably participate in that weakness, or mode of atrophy, through which, in young persons, the vertebral column becomes laterally bent.

d, Fibro-cartilages generally, it may be presumed, are susceptible of inflammation. The only instance, however, in which I have found this demonstrable, occurred in the semilunar cartilages of a knee-joint. Ulceration of the cartilages covering the bones had taken place, with high inflammation of the adjacent surface of the bones, and of the capsular synovial membrane. The semilunar cartilages (the knee having been injected after amputation) were red with the vermilion, swollen, softer than natural, and when divided, shewed, upon the section, extremities of cut vessels.

e, Ulceration and suppuration may occur in fibro-cartilage. In a case communicated by Mr. Howship to Sir Benjamin Brodie, in which, upon dissection, no remains were found of the intervertebral cartilages between the tenth and eleventh dorsal vertebrae, nor between the third and fourth lumbar—these intervertebral spaces being filled with pus, and the opposite surfaces of the vertebrae being carious, but only to a small extent—the *central part* of the intervertebral cartilage, between the ninth and tenth dorsal vertebrae, had been completely absorbed, and pus was found in its place. Externally to this the concentric

layers of elastic cartilage were entire, though somewhat altered from their natural appearance.

f, Portions of fibro-cartilage sometimes become detached in the progress of ulceration; they are then dead parts—irritants to the parts adjoining. It is conceivable that they may sometimes cease to be alive before their adhesion to the neighbouring living substance is destroyed.

3d, The affections of ligament will be more fully considered in the next lecture. It is sufficient to mention at present that the ligaments are readily repaired when torn; that they are susceptible of atrophy and elongation—of inflammation, softening, ulceration, sloughing.

The diseases of the vertebral column admit of being classed under two heads—atrophy, namely, and inflammation. To the first head belong weakness of the spine in young persons, the yielding and curvature in rachitis, and the softening in mollities ossium. Of the nature of these cases I have briefly spoken in a former lecture. Under the second head may be considered those instances which are usually classed together by the term spine disease. In introducing this principle of classification, however, I am bound to state that there is not evidence enough to authorize me in asserting, as a thing proved, that all cases of spine disease are produced by inflammation, although I strongly anticipate that this will be found to be the fact. Sir Benjamin Brodie, who has contributed in so great a degree to the elucidation of the diseases of joints, does not appear to admit this view of the subject. After drawing an important distinction, which originated, I believe, with him, between cases where the vertebrae are first affected, and cases in which the intervertebral substance is the part primarily diseased, he notices, as a *third division*, “another order of cases, but of more rare occurrence, in which the bodies of the vertebrae are affected with chronic inflammation, of which ulceration of the intervertebral cartilages is the consequence.” My own impression is, that all these affections begin with inflammatory action; sometimes affecting a single bone; sometimes two or more adjacent bones; sometimes the whole extent of the vertebral bones; sometimes affecting the fibro-cartilages alone; sometimes attacking both systems at once:—but in every case leading eventually to ulcerative disease of both, that affords evidence by the greater ravage it has committed of one or other tissue, as to which was primarily affected.

The two following cases exemplify commencing inflammatory disease of the vertebral column:—

A young lady, when wheeling a heavy garden-chair, was conscious of having strained her back, but the sensation went off. In a few days, however, she found that the least exercise brought on pain in the lumbar portion of the spine. This was followed by pains in the left thigh and leg, which subsequently extended to the right. Two months after the complaint began, I saw this patient: there was no irregularity of the spinous processes of the lumbar vertebræ, or tenderness on pressing the adjacent region; pain only, and a sense of weakness, were present. By perfect quietude, and preserving the horizontal posture almost constantly, joined with the use of caustic issues applied over the seat of pain in the loins, this patient, in a year, was entirely restored.

A young woman was admitted an in-patient of the Middlesex Hospital, with the following symptoms. She suffered constant pain in the whole length of the vertebral column, which, when lightly struck, communicated a sensation of soreness through the bones. There was no projection of the spinous processes at any point; her right side, and right arm and leg, were deficient in sensibility, and were weaker than the left. There was some incontinence of urine. She was kept in the recumbent posture, was cupped on the most tender parts of the spine, and had issues made with the moxa: calomel was likewise given to touch the mouth. By a long pursuance of this treatment she eventually recovered.

I cannot better exemplify the conditions into which the vertebral column falls under spinal disease, than by extracting from Sir Benjamin Brodie's work, on the Diseases of Joints, the following account of three dissections:—

On examining the body of a young man, "no remains were found of the intervertebral cartilage between the fourth and fifth dorsal vertebræ, and the opposite surfaces of these two bones were consumed by caries to some extent, but more upon the left side than upon the right. The intervertebral cartilage between the eleventh and twelfth dorsal vertebræ had also entirely disappeared, and the opposite surfaces of these bones were in a state of caries; but this had not extended itself sufficiently to occasion any sensible loss of bony substance. The intervertebral cartilages between the third and fourth, fifth and sixth, seventh and eighth, tenth and eleventh, dorsal vertebræ, and also that between the twelfth dorsal and first lumbar vertebræ, were all found in a perfectly natural state towards the circumference, but in the centre they were of a dark colour; and on the surfaces, towards the bones, they, as well as the bones them-

selves, were in a state of incipient ulceration, but without any appearance of pus having been secreted. All the other intervertebral cartilages were in a natural state, and the bones of the vertebræ every where had their natural texture and hardness. On laying open the theca vertebralis, the membranes of the spinal marrow were found adhering together, behind the space between the fourth and fifth dorsal vertebræ."

"On examining the body of a young woman, ætat. 19, the bodies of the three or four inferior lumbar vertebræ were found preternaturally vascular, and of a dark and almost black colour; but they retained their natural texture and hardness. The intervertebral cartilages were in a natural state, but the body of one of the vertebræ was superficially ulcerated, for about the extent of a sixpence, on one side, towards the posterior part. A large abscess communicated with this ulceration, and occupied the situation of the psoas muscle of the left side, extending downwards to the groin."

"On examining the body of a man, ætat. 45, the cancellous structure of all the dorsal and lumbar vertebræ was found of a dark red colour, and softer than natural, so that they might be cut with a common scalpel, or even crushed by the pressure of the thumb and fingers. The opposite surfaces of the bodies of the second and third lumbar vertebræ, and of the cartilage between them, at the posterior part, were extensively destroyed by ulceration. Anteriorly, the bones and the intervertebral cartilages were entire, and the latter was in a perfectly natural state; but the bones throughout were of a dark and almost black colour."

The features of spinal disease are obvious and necessary consequences of the morbid changes which have been described.

The vertebral column, attacked with inflammation of the bones or fibro cartilages, becomes the seat of sensations of weakness, pain, and tenderness.

The bony or cartilaginous substance of the vertebral column, being absorbed in front, causes the spine to bend forwards, and the undiseased bony arches to project backwards.

The vertebral column, being weakened by absorption of one or other of its constituents, is liable, on any sudden violence, to give way suddenly, and so to become suddenly bent at the ulcerated part. In the majority of instances, the curvature takes place very gradually.

The spinal marrow, being either compressed by the flexure of the vertebral column, or irritated by contiguous sympathy, diminution of sense and motion of the lower part of the frame, with

spasms, and pains of the legs, and incontinence of urine, and constipation of the bowels, are liable to follow.

Finally, as another consequence of contiguous sympathy, there are liable to occur in the adjacent cellular tissue extensive formations of matter, which point either in the loins or at the groin, under the names of lumbar or psoas abscess.

It is found by experience that lumbar and psoas abscesses rarely occur except in connexion with disease of the vertebrae. To this connexion of disease the attention of the surgeon is at once directed, whenever matter is found to point in the lumbar region or the groin. When such an abscess has taken place, it commonly marks an advanced stage of spine disease; but it is sometimes possible, even at this period, by appropriate remedies, to relieve at the same time the disease of the vertebral column and the abscess which it has occasioned.

Disease of the pelvic joints is of very unfrequent occurrence. At the time of labour, an affection occasionally takes place in these joints, which is sometimes distinctly inflammatory, while at other times it bears the character of simple absorption of the fibro-cartilage. I witnessed an instance in which, after labour, an abscess formed behind the symphysis pubis, which was followed by a sense of weakness and giving of the pubic joint, which lasted several weeks, but gradually went away. Cases of this description are, I believe, far from uncommon. In others, the sacro-iliac joints are principally affected; there is no suppuration, but extreme weakness at these joints, which lasts many months. The patient is obliged for a long period to keep the recumbent posture; and then, and afterwards while recovering strength, derives remarkable comfort, and a sense of support, from bandages round the pelvis.

The following case, which was under my care, exemplifies commencing disease in the sacro-iliac synchondrosis, brought on by external violence.

A gentleman was riding in Hyde Park, when his horse reared, and fell backwards, bearing him to the ground. He was lifted by those around, when he found himself capable of walking, with assistance. I saw him a short time after the accident. The only part bruised was the integument covering the back of the sacrum, and more to the right side than the left. There was no fracture that I could ascertain—nothing but the bruise; and, as it afterwards appeared, a strain of the right sacro-iliac joint. The patient could bear the ilium to be pressed in any direction, and could, as I have mentioned, both stand and walk. In the evening considerable pain came on; he was cupped upon the hip, and experienced relief.

The following day the cupping was repeated. After a month, during which this patient had kept his room, and the pain had nearly left him, he went, for change of air, to Richmond, when a child accidentally touching his foot, as he lay on a sofa, he drew up the limb suddenly. Upon this he experienced a sensation which he described to be like displacement of the bones at the right sacro-iliac joint; and he fancied he recollected that at the time of the accident he had felt a similar sensation: but certainly neither then, nor at this time, did pressure upon the ilium, in a direction to strain the sacro-iliac joint, bring on this sensation, or cause any thing like sensible motion of the joint. The pain now became gradually very severe, and extended down the limb, in the course of the sciatic nerve.

It was a year and a half from the occurrence of the accident before this patient had recovered. In this period many remedies were tried: those which were most beneficial were, strict observance of rest, and the application of caustic issues over the joint. When by these means the pain had been entirely subdued, cold sea-bathing rapidly restored his strength.

PRIZES FOR BOTANY,

PROPOSED AND ADJUDGED BY THE SOCIETY OF APOTHECARIES. 1831.

[An appeal has been made to us relative to the late decision of the botanical prizes: and from what has been stated to us, on very respectable authority, some of the unsuccessful candidates have reason to complain. The examination, it seems, is twofold—written and oral. The gentleman who obtained the first prize, it is admitted, was the best answerer in writing; but not to such a degree as to counterbalance his very inferior oral answering. It is suggested that more weight should have been attached to the latter ordeal—which is, in fact, the practical, and perhaps the more valuable part of the examination—it being quite possible to be made up for the other part by mere book knowledge. We will not enter into a detail of the particular merits of the answering: but some of our readers may perhaps be glad to see the list of questions proposed to the candidates on the occasion.—*Ed. Gaz.*]

Questions for Written Answers.

1. What are the more ordinary forms assumed by vegetable tissue?
2. Are the various modifications of this tissue separated by well defined limits, or are they found to pass into each other?

3. What is the structure of the cuticle, and of what nature are those bodies called stomata which appear upon its surface?

4. Are you acquainted with any organs destitute of cuticle?

5. Do the ascending and descending axes of a plant differ anatomically?

6. Of what is the medullary sheath composed?

7. What are meant by medullary rays?

8. Is the presence of buds essential to the generation of wood?

9. Are the celluloses wholly destitute of spiral vessels and tubes?

10. What are the essential functions of a leaf?

11. In what respect do the leaves of the celluloses differ from those of the more perfect plants?

12. On what grounds is the theory which derives the various parts of a flower from the leaves to be supported?

13. What are the effects produced by etiolation?

14. What is a bulb?

15. What is the nature of the tuber in the potato, and how is it distinguished from a rhizoma?

16. On what do the various forms of leaves depend?

17. Do petals differ anatomically from leaves?

18. What is the nature of that kind of inflorescence called a spike, and what would it become if its axis were depressed?

19. What is the nature of a cyme; and if its general axis were elongated, what would result?

20. To the axis of what kind of flower is the term torus applied?

21. What is a perfect flower?

22. What is a multilocular fruit?

23. What are the essential parts of a seed?

24. What kind of aestivation is of the most frequent occurrence in the polypetalous corolla?

25. The Linnean classes, and on what founded?

26. The Linnean orders, and on what founded?

27. What are the primary sub-divisions of the vegetable kingdom, according to the system of natural affinities; and what are the chief anatomical differences in those divisions?

28. What are the prevailing numbers amongst the two first sub-divisions of the vasculares?

29. Is the presence of albumen universal in any group you are acquainted with?

30. What are the functions of the cotyledons, and do they appear to be necessary only to such plants as derive their nourishment from the earth?

31. What is the Linnean class and order of iris, and the natural family to which it belongs; and how does that differ from hemodoraceæ and amaryllidæ?

32. — colchicum and natural family; and how does that family differ from smilacææ and liliacææ?

33. — narcissus; and how is the family distinguished from liliacææ?

34. — daphne and natural family; and by what characters is this family separated from proteacææ?

35. — digitalis, and its natural family?

36. — atropa? Distinguish the genus from hyoscyamus, and the family from digitalis.

37. — menyanthes, and natural family? Distinguish the genus from the rest of its order, and how separated from apocynææ?

38. — cinchona, and natural family; and how distinguished from caprifolia and apocyma?

39. — earum? Add the structure of the fruit and seed, and the names of the more poisonous plants of the order.

40. — helleborus, and natural family; and how is that family separated from trollius?

41. — citrus, and natural family; and how separated from meliacææ?

42. — acacia, and natural family; and how is it distinguished from most of the other orders?

43. — eroton, and natural family; and what is the structure of the fruit and seed?

44. — pipper, and natural family; and are they with or without albumen; and by what means is the family distinguished from urticææ?

45. — junicerus, and natural family? What is the nature of the fruit, and what are the peculiarities of the structure in the reproductive organs in this family?

COMPARATIVE IRRITABILITY OF THE RIGHT AND LEFT PORTIONS OF THE HEART.

M. CASTEL lately gave an account, in the Académie de Médecine, of some observations made by him and M. Amussat, concerning the much greater supply of nerves to the right than to the left side of the heart; whence the former preserves its irritability so much longer than the latter. M. Hippolyte Cloquet supported this view, and mentioned that the right portion of the heart receives eight or ten nervous branches, while the left is supplied with no more than four or five; a fact already noticed by Scarpa, and Walter of Berlin. — *Gaz. des Hôp.*

ABORTION EXTRAORDINARY.

FŒTUS VOMITED BY A BOY.

A GREEK journal, the *Soter*, of the 31st August last, contains an account, drawn up by Dr. Ardoin, of a foetus vomited by a boy, named Demetrius Stamattelli, a native of Syra. M. Ardoin was called in to attend the patient, who was suffering from pains of the stomach and bowels. The symptoms were so serious as to threaten the boy's life. However, the Doctor ventured on an *emetico-purgatif*, consisting of castor oil, an ounce; syrup of coraline and syrup of ipecacuanha, half an ounce each; exhibited in a pectoral decoction by way of julep. Violent cough and vomiting were produced, in the course of which the young Demetrius threw up the aforesaid foetus. It is described as an embryo of from forty to fifty days: the head and one arm well formed, but, in lieu of the lower extremities, the body contained in a sheath, which runs as a cord to the placenta. The boy recovered, and the phenomenon has been regularly put up in a bottle. M. Ardoin has of course taken care, by the presence of witnesses, to assure the curious and to satisfy the sceptical that there has been no mistake.—*Abridged from the Gaz. des Hôp.*

MANSLAUGHTER BY DISPENSING IMPROPER MEDICINE.

In a case which recently happened in France, of three children being killed by the negligence of a pharmacist and the ignorance of his pupil, who gave corrosive sublimate in place of calomel, ordered in a physician's prescription, sentence has been passed on the accused. Estienne, the pharmacist, is fined 600 fr. with costs; Brandilly, the pupil, to be imprisoned a month; and both to make up between them the sum of 2000 fr. as damages, payable to the father of the children.

MEDICAL STUDENTS IN PARIS.

The inscriptions for the present season, up to the 15th November, have been 2519. The entire number of students is reckoned at 3500.—*Gaz. des Hôp.*

LITERARY INTELLIGENCE.

In course of publication, at Brussels, *Cours complet d'Histoire Naturelle Médicale et Pharmacologique*; appearing in Paris. To form, when complete, two 8vo. volumes, with an Atlas of 150 plates.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO RECEIVED CERTIFICATES DEC. 11, 1834.

Henry Hayward, Aylesbury.
Anthony Dolce, Aylesbury.
Charles Goodwin, Norwich.
John Hughes, Hanrwt.
Charles Stokes, London.
Wm. Thomas Dalby, Bow, Middlesex.
Edward Henley Finley, London.
Charles M. Dermott, London.
William Jones, Henley in Arden.
Joseph Blackshaw, Stockpo t.
William John Gage, Sheffield.
Henry Elsegood, London.

WEEKLY ACCOUNT OF BURIALS,

Increase of Burials, as compared with } 1070
the preceding week

* The great increase in the number of burials inserted in this week's Bill of Mortality, has arisen from several of the clerks of large parishes having withheld their reports till the close of the year; from the same circumstance is to be imputed the seeming increase of deaths by cholera.

METEOROLOGICAL JOURNAL.

Dec. 1834.	Thermometer.	Barometer.
Thursday	from 40 to 51	30 16 to 30 14
Friday	29 45	30 07 30 03
Saturday	30 50	30 60 30 02

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

BY THOS. DAVIES, M.D.

LECTURE XII.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

EMPHYSEMA PULMONUM.

WE define emphysema pulmonum to be a dilatation of the air cells of the lungs, or an infiltration of air into the cellular substance which separates the lobules of that organ from each other. The first species may be called *vesicular emphysema*, the second *interlobular emphysema*.

VESICULAR EMPHYSEMA.

Morbid anatomy.—The size of the aerian vesicles increases from the slightest addition to their volume, to the magnitude of a grain of millet-seed—to the kernel of a cherry—to a bean; or they may enlarge, in extreme cases, to a capacity sufficient to hold a pint of fluid. In the latter cases this great development is due to a rupture of a vast number of cells into each other; for you may see the *debris* of their partitions upon the inside of the transparent parietes of the unilocular cavity formed by them.

[A number of beautiful specimens of vesicular emphysema were now exhibited, in which the cells were seen dilated from the size of a millet seed, to a volume whose capacity would contain more than a pint of fluid.]

The smaller dilated cells do not project beyond the surface of the lungs, the larger ones usually do; the latter presenting the vesicular appearance of blisters. These large projecting cells are often globular, and sometimes pediculated; but the pedicles are only formed by strangulations of the cells, where the vesicles emerge from the pulmonary substance; and in cutting into them, and passing a probe through the pedicle, as large a cavity will be found embedded in the substance of the organ as there is projecting beyond it. At the bottom of the dilated cells you perceive here, gentlemen, several dark orifices, which are the openings of communication with the surrounding air vesicles. It is clear, as Laennec has observed, that these dilatations do not depend upon extravasations of air, because of the continuation of their cavities into the substance of the lung, and because they cannot be pushed by the finger from point to point under the pleura. It, however, does occasionally happen, that in consequence of the rupture of the cells, the air passes into the interlobular cellular tissue, and beneath the pleura, forming irregular vesicles of various sizes, which may be displaced by the finger, but they have no depressions in the substance of the lungs corresponding with them, like the previously described species.

Although it be rare for the air to permeate the interlobular cellular tissue, or the cellular substance surrounding the bronchial tubes and great blood-vessels, yet such may be the distention of the central aerian cells, that their bursting may occasion a rupture of the pulmonary tissue; then the part of the lung corresponding to the rupture will be seen largely swollen; and on cutting into it at this place, to a greater or less depth, a cavity will be found from whence air will escape, this cavity often containing a little blood, generally coagulated, but always small in

quantity compared to the space in which it is contained.

The bronchial tubes, particularly the smaller ones, communicating with the dilated cells, are occasionally, although not frequently, dilated also.

There are two modes of preparing specimens of emphysema pulmonum; the one by forming a dry, the other a wet preparation. To make a dry preparation, the lung should be well distended by insufflation, and the bronchial tube, through which you have distended, should then be firmly tied, and the specimen be dried pretty quickly. You will soon find that your preparation will shrivel and contract, from the escape of air through some imperceptible orifice; it becomes, therefore, necessary to renew the insufflation during the drying several times. When quite dry it should be varnished, and sections made by a sharp razor or scalpel, and the dilated cells will thereby be very well shewn. The other mode is effected by immersing the emphysematous lung in spirits of wine. A preparation of this sort requires a large weight to keep it down in the bottle, in consequence of the buoyancy of the organ from the increased quantity of air it contains. You perceive, gentlemen, that this preparation, contained in a vessel not holding a pint and a half of liquid, requires above two pounds of mercury to keep it at its proper level.

Vesicular emphysema may affect a part of a lung, the whole of a lung, or both lungs. When the disease is extensive, the moment you elevate the sternum a part of the organ escapes from the chest, as if there was not sufficient room for it, and projects externally, instead of subsiding as it usually does. The lungs now feel to the hands like a down pillow; they give the impression of greater firmness than natural; the crepitation, upon pressure, is of a different character; and if an incision be made, and the air pressed out, a sound is produced like air passing slowly through a bellows. Laennec believes these phenomena to arise from the communication between the air cells and the bronchial tubes being less free, or from a diminished flexibility of the parietes of the vesicles, or perhaps from a combination of these two causes.

An emphysematous lung swims on water almost like a bladder distended with air. The pulmonary tissue is usually drier in an emphysematous than a healthy lung; exceptions to this are rare.

When one lung only is affected, it is much more voluminous than the other; in that case it may press the mediastinum and the heart from their natural positions, and even enlarge the side of the chest corresponding to the diseased organ.

Emphysema pulmonum had been indistinctly seen by several authors, as Bonetus, Morgagni, Van Swieten, and Storck. Sir John Floyer, in the appendix to his *Treatise on Asthma*, gives an account of the disease in a broken-winded mare. Ruysch and Valsalva had seen dilated air cells; and Baillie has given a good description of them. Laennec's account of the disease, which I have almost given literally, is, however, by far the most minute and correct.

Causes of vesicular emphysema.—Laennec, in the year 1823, gave, in his lectures at the "College de France," the following explanation of the physical causes of this disease:—

Vesicular emphysema almost always develops itself in consequence of intense, extensive, or long continued dry catarrh. Almost all asthmatics from that form of catarrh, present, upon post-mortem examination, a dilatation, more or less marked, of the air cells. I never saw any patient affected by dyspnoea, from any cause, of a few years' standing, without detecting this disease in various degrees. Laennec observes, that, in dry catarrh, the small bronchial tubes are often completely obstructed, either by pearly spota or by the swelling of their mucous membrane: and as the inspiratory muscles are strong and numerous, their action is sufficient to overcome this obstruction, so that the air can pass with more or less freedom into the cells, where it becomes, as it were, imprisoned, in consequence of the expiratory power being insufficient fully to force it back again through the obstruction. A long succession of inspiratory acts will, under these circumstances, at last permanently dilate the air-vessels to an extent proportionate to the degree and duration of the obstructing cause. We must also recollect that the atmospheric air is introduced into the lungs at a temperature much lower than that of those organs, so that it dilates in proportion to the increased heat, and consequently must tend to dilate the cells in which that air is contained. It follows, from what has been said, that dry catarrh ought mechanically to produce vesicular emphysema, as much as chronic mucous catarrh leads to dilatation of the bronchial tubes.

There are some other causes which may produce this disease: thus players upon wind instruments are often obliged to retain the air forcibly, and for a long time, in the air-cells, and thereby occasion their dilatation. Certain other violent respiratory acts may also be considered as causes; but these I shall particularly refer to in speaking of interlobular emphysema.

Any cause also which prevents the free emergence of the air in expiration, may

produce vesicular emphysema: thus tumors developed in the bronchial or mediastinal glands, or aortic aneurisms compressing the bronchi; tumors of a certain size formed in the lung itself—as cysts, or masses of tubercles—will partially produce this effect.

There is another cause, which Laennec has not noticed, which I have seen acting in two or three instances. In consequence of extensive disease in one lung, the puerile respiration sometimes becomes so extreme in the other as to occasion the air-cells to dilate. The following remarkable case exemplifies this fact.

I was called to a child of five or six years of age, labouring under very severe dyspnoea of a few days standing, in whom the face had become livid, the pulse lost, and the extremities cold. Every thing indicated approaching death; indeed the child expired a few hours after I saw it. Such was the distress of the little sufferer, that I would not add to it by making a useless local examination of its chest. Upon a post-mortem examination, we found that percussio afforded a very dull and fleshy sound on the left side, whilst the right was exceedingly sonorous. On opening the pectoral cavity, the left lung was found to be hepatized to nearly the whole of its extent—a circumstance already sufficiently rare in so young a child. The right lung was depressed in the chest, and of nearly one-third its original volume, and covered by large vesicles, presenting the appearance of a number of elevated blisters upon the surface of the organ. The space in the chest unoccupied by the lung was filled with air, part of which had escaped, with a hissing noise, upon the first incision made through the ribs of the right side. The lung itself, when taken out, presented a most beautiful specimen of vesicular emphysema.

No doubt, in this case, the hepatization of the left lung had increased the necessity for respiration in the right—a necessity already great from the age of the child. Its natural puerile respiration became so intensely developed, the energy of the function so extraordinarily great, as to largely dilate the air-cells of the healthy lung. Some vesicle must have ruptured, perhaps by a very minute orifice, so that a certain quantity of air passed in every inspiration into the cavity of the pleura, and, by its gradual accumulation, pressed upon the lung, and diminished it to the volume I have mentioned. We had, therefore, in this case, vesicular emphysema of one lung, in consequence of hepatization of the other, and pneumo-thorax as a result of the emphysema.

SYMPTOMS OF VESICULAR EMPHYSEMA.

Functional and general signs.—Dyspnoea invariably occurs when the disease has become somewhat considerable: the reason is obvious. The expiratory act cannot expel a sufficient quantity of air at each movement, so that too great a proportion remains in the cells, deprived of its oxygen, and preventing by its presence a complete renewal during inspiration. The mode of respiration is peculiar; in extreme cases, you will see the patient expand his chest in every direction, as if he were endeavouring, by a strong effort, to sweep out and displace the vitiated air contained in his lungs.

Various causes may augment the dyspnoea; as flatulence of the stomach or intestines, preventing the free descent of the diaphragm—emotions of the mind—exercises of the body, as running, hard working, &c., by which the blood is sent with too great rapidity to the lungs.

The dyspnoea finally becomes constant; but it will sometimes be considerably aggravated by a fresh inflammation attacking the already-obstructed bronchial tubes, or by a spasmodic action of them. When this occurs, then it constitutes a form of dry asthma, which we shall hereafter describe. After the asthmatic paroxysm is over, the ordinary state of dyspnoea returns.

As the blood does not flow freely through the lungs, venous congestions have a tendency to form; thus, at last, the skin presents an earthy tint, often mixed with a dull violet or lead colour. The veins on the surface frequently enlarge, the lips appear thick and swollen, and of a leaden hue; and, according to my observations, emphysematous patients are more disposed to sleep, particularly after a meal, than others; probably from a greater disposition to temporary cerebral venous congestion.

There is generally habitual cough—often however infrequent, slight, and dry. If there be expectoration, it is usually viscous and transparent: the cough is rarely violent, or followed by mucous sputa.

The constant obstruction to the free passage of blood through the lung, ultimately occasions hypertrophy and dilatation of the heart.

Local signs.—When emphysema attacks one lung only, or when it exists much more considerably on one side than the other, then the diseased side is evidently the most voluminous. If both sides are equally affected, the chest presents at once a globular and a cylindrical form; being swollen before and behind, instead of being somewhat depressed in those situations.

By *percussion*, a much louder sound than natural is elicited, in consequence of the great accumulation of air in the lungs.

The respiratory murmur is very imperfectly heard in an emphysematous lung; now and then a sibilating sound, or a sound like the clicking of a small valve, may be distinguished, indicating the presence of pearly sputa.

But when the disease is intense, then there is a sign which is pathognomonic: it consists in a species of dry crepitating sound, before described under the name of *rhonchus crepitans*, with large bullæ; it is a sound heard when the patient coughs or inspires strongly, like air blown into half-dried cellular tissue. It differs from the ordinary crepitation of *peripneumonia*, or oedema of the lungs, by its carrying with it the sensation of dryness, and by the greater size and inequality of the bullæ which compose it.

This phenomenon is rare, and of short duration: it is heard only for a few moments, and to a slight extent. It is much more common in interlobular emphysema: some patients feel a crackling at the point affected at the moment the crepitation is heard; sometimes, though rarely, the vibration of the sound is communicated to the hand pressing the parietes of the chest.

Progress of the Disease.—Laennec observes, that this organic alteration of the cells most commonly arises from the grafting of acute dry catarrh upon the chronic form; and dry catarrh being, of all others, that which is most accompanied by tumefaction of the bronchial mucous membrane, it may readily be conceived how an obstruction of the smaller tubes may produce a dilatation of the aerian vesicles.

The frequent returns of acute dry and latent catarrhs, often induce an asthmatic paroxysm; but these are not the sole causes of this affection, as we shall hereafter see.

If, upon chronic dry catarrh, the acute form supervenes, the dyspnoea becomes almost suffocating. This oppression diminishes if fever co-exists, or a pituitous or mucous expectoration appears. The pearly sputa become less tenacious, and are carried from the bronchial tubes by the more liquid secretion which accompanies the recent catarrh. But if the fresh accession of catarrh leads to no ultimate relief of the chronic disease, then the attack will be prolonged; it finally gradually diminishes, and often leaves the patient more oppressed than before. Violent attacks of dry asthma occur at long intervals during the first few years; but if the emphysema has been of long duration, and as old age approaches, the accessions approximate more

closely, and become of greater intensity; each of them increases the extent of the dilatation of the air cells, which in these cases sometimes rupture, and produce the interlobular form of the disease.

Treatment.—We have but little to say upon this subject. The indications here are to subdue the dry catarrh, which is the mechanical cause of the emphysema, and then to diminish the volume of the enlarged vesicles. To fulfil the first indication, the same treatment must be adopted that I have recommended for dry catarrh, which it is needless here to recapitulate; I refer you to the lecture upon that subject. I know of no possible means of fulfilling the second indication, that is, to diminish the volume of the emphysematous air cells, for they have been subjected to an organic change, and the present state of science affords no means by which that change can be obviated.

INTERLOBULAR EMPHYSEMA.

Vesicular emphysema is generally a chronic affection; interlobular emphysema is a sudden and acute disease, the result frequently of accident.

Morbid Anatomy.—Dense as the cellular tissue is which separates the pulmonary lobules, yet it occasionally becomes infiltrated with air. These slight partitions now increase in breadth, from a line to five or six lines, or even an inch, forming, particularly towards the edges of the lungs, transparent bands, plunging more or less deeply into their substance. These bands are broadest at the surface of the organ, and become gradually narrower as they descend towards the centre. They sometimes run parallel; at others, traverse each other, so as to isolate one or many lobules, according to the extent of their intersections. Small grains, as it were, of air, run frequently in the cellular tissue surrounding the blood-vessels and bronchial tubes, often also extravasating beneath the pleura; and when the air penetrates to the root of the lungs, it passes from thence into the mediastinum, and so to the neck, and the cellular tissue of the rest of the body.

It might be supposed that this disease could only arise from the rupture of a number of cells, and that the air passed from thence into the surrounding cellular tissue. It may be so; but the broken cells have not yet been detected, nor are the vesicles contained in the isolated lobules even dilated.*

Sometimes the mass of air is so broad in the interlobular cellular tissue, that it is difficult to suppose that it has not infiltrated into the whole of a lobule, and by insinuation between the cells, compressed

them, and occasioned them thereby to be reduced to their mere cellular rudiment: yet no positive evidence exists of this circumstance.

Causes of Interlobular emphysema.—Any cause by which the air is retained a long time, and with violent effort, in the lungs, may induce this disease—as the resolute attempt to lift too great a weight, the efforts of accouchement, of defecation, &c.

Can air be generated spontaneously in the interlobular cellular tissue? It is possible; for we see exhalations of gaseous fluids occur in cavities where no communications exist with the external air—as in the peritoneum, pericardium, and within the synovial membranes.

It would appear surprising, considering the extreme dyspnoea which occasionally takes place from vesicular emphysema, that the dilated cells do not rupture, and produce the interlobular species: this, however, has never yet been seen. It is true that sometimes a little air will escape under the pleura; and I have seen an instance of the cells rupturing through the pleuritic covering of the lung, inducing pneumo-thorax; but I believe no instance is known of vesicular emphysema producing interlobular. This, in all probability, is due to the increased firmness of the cells when permanently dilated, and to the extreme density of the interlobular cellular substance.

Local Signs of Interlobular Emphysema.—The dry crepitation with large bullæ is the pathognomonic sign of this disease. The “frothing ascent and descent” are also signs: the first occurs at the moment of inspiration; and at this time, too, the crepitation may be distinguished: the second accompanies expiration. It is sometimes heard once, and at one moment only; at others, two or three times successively; occasionally, only when the expiration is completed, and it then appears as if something descended into its usual situation. Usually the rubbing seems to be against the costal pleura; now and then against the diaphragm, or deeply against the mediastinum, or among the pulmonary lobules. A crackling at the affected part is often felt by the patient.

These sounds often communicate their vibrations to the hand. The crepitation may even be produced occasionally by pressing the finger against an intercostal space, corresponding to the part of the lung affected.

By percussion you may always elicit a loud sound, except there be any co-existent pulmonary engorgement at the emphysematous part.

If the emphysema attack the neck, then, by pressing the part, crepitation is pro-

duced, and the diagnosis becomes still more complete.

General and functional signs.—Sudden dyspnoea after the occurrence of any of the above-mentioned causes. Infants are most commonly attacked with this disease: thus it may occur in them as a consequence of croup, or of severe catarrh. It may occur also in adults, although not so frequently, under the same circumstances.

Treatment.—Very little can be done in this disease, and fortunately it is an affection which has rarely any serious results. When the air infiltrates into the subcutaneous cellular tissue, a few punctures with the lancet will be ordinarily sufficient to allow of its escape. When the disease is confined to the lung, in every case the air appears to be absorbed, and the interlobular cellular septa return gradually to their natural size.

THE ANATOMY AND PHYSIOLOGY OF THE LIVER.

By FRANCIS KIERNAN, ESQ.

Member of the Royal College of Surgeons, late Teacher of Anatomy.

[Concluded from p. 374.]

Of the lobular arteries.—The lobules are sparingly supplied with arterial blood. These bodies cannot be coloured with injection from the artery, even in the young subject; in the adult, after the most successful injection, when the arteries of the cellular capsule, those of the excreting ducts and gall-bladder, and the vasa vasorum are minutely injected, a few injected vessels only are detected entering the lobules. I have frequently tied the thoracic aorta in living animals, thereby cutting off all supply of blood from the abdominal viscera; and in these animals, when injected from the aorta below the ligature forty-eight hours after death, the integuments, the secreting portions of the kidneys, the spleen, pancreas, intestines, and pelvic viscera, were coloured in a remarkable degree by the injection; on the surface of the liver a few vessels only could be discovered, this organ presenting a curious contrast with the surrounding coloured viscera. The gall-bladder and ducts were, however, equally well injected with the intestines; the vasa vasorum were also well injected. In these experiments it will be remarked that the secreting portion alone of the kidney was highly injected; the excreting portion of this gland resembling the secreting portion of the liver in its sup-

ply of arterial blood, which it receives for nutrition only. Similar experiments were tried on birds, and in these animals all the viscera were highly injected, with the exception of the liver and kidneys, the latter organs in oviparous animals having, like the liver, a double venous circulation, the urine, as well as the bile, being secreted from venous blood. Whether the liver be injected from the aorta, or from the hepatic artery, the appearances produced will be nearly the same. In speaking of the excreting ducts, it was shewn that these vessels are abundantly supplied with arterial blood, which is received by branches of the portal vein; the injection very commonly passes from the arteries into these branches, and thence into the trunks of the vein, and it occurred to me, that the injection thrown into the arteries was probably in this manner diverted from the lobules. To ascertain if such was the case, blue injection was first thrown into the portal vein; the arteries were then injected with red. On dissection, branches of the two sets of vessels were found in the coats of the vessels, and in those of the excreting ducts and gall-bladder; the lobules were coloured with the blue injection; the red was confined to their circumference, and appeared in points only. This experiment was varied, by injecting the portal vein and its branches as far only as the entrance of the latter into the lobules, these bodies thus remaining uninjected. The injection propelled through the arteries had now free access to the uninjected lobules, and no exit by the injected portal vein; and the artery having no communication with the hepatic veins, the injection had no exit by these vessels: the lobules, however, were not better injected in this than in the preceding experiments. From these experiments I conclude, that the secreting portion of the liver, like the excreting portion of the kidney, is supplied with arterial blood for nutrition only. As all the branches of the artery of which we can ascertain the termination end in branches of the portal vein, it is probable that the lobular arteries terminate in the lobular venous plexuses formed by that vein, and not in the intralobular branches of the hepatic veins, which cannot be injected from the artery, the blood of these arteries, after having nourished the lobules, becoming venous, and thus contributing to the secretion of the bile.

Müller is also of opinion, that the ultimate reticulated vessels of the liver receive blood from the artery as well as from the portal vein.

Of the red and yellow substances of Ferrein, and of the appearances produced in the liver by congestion.—The structure of all the lobules

is similar, and each lobule is of the same structure throughout; one part of a lobule is not more vascular than another; there is, therefore, no distinction of red and yellow substances in the liver; the red colour results from congestion only. Ferrein's opinion respecting the existence of two substances has been very generally adopted by anatomists; some, however, have disagreed with him respecting their relative position to each other.

My attention was first directed to the anatomy of the liver by the study of the admirable works of M. Andral. In the first organs I examined, I found the small branches of the hepatic veins ramifying exclusively in the red, and those of the portal vein in the yellow substance. I concluded that the liver was composed of two venous trees, a portal and an hepatic tree, the former having a cortex of yellow, the latter of red substance; and, with M. Boulland, I thought it probable that the red substance was the organ of the function imagined by Bichat. I next ascertained the lobular structure, and concluded with Ferrein that the red substance was medullary, and the yellow cortical. Subsequent dissections, in which I found branches of both the portal and hepatic veins ramifying in the red substance, tended to unsettle the opinions I had formed respecting the anatomy and physiology of the two substances; and these opinions were finally overturned by the examination of a liver in which I found the branches of the portal vein alone ramifying in the red, and those of the hepatic veins in the yellow substance. The only conclusion that could be drawn was, that the red colour resulted from congestion; that it was medullary, occupying the centre of each lobule, when the hepatic, and cortical, forming the circumference, when the portal vein, was congested. It occurred to me that the kidneys of birds having, like the liver, a double venous circulation, were equally subject to congestion, and would, like it, present an appearance of two substances. Dissection verified this conjecture; but the apparently two substances are red, one, however, being of a much deeper colour than the other. I have satisfied myself by repeated injections, by examination with the microscope, and by experiments on living animals, that the lobules are of the same structure throughout; that one portion of a lobule is not more vascular than another; that the acini of Malpighi, by contrast with the congested vessels, are even more apparent in the red than in the yellow substance; and that these supposed two substances are consequently identical in structure. That secreting biliary ducts are contained in the

red as well as in the yellow substance, is proved by the relation given by M. Andral of a case of jaundice, with "coloration insolite du foie." "Foie volumineux, pesant, très-dur, se déchirant difficilement, offrant une teinte générale d'un brun verdâtre. En l'examinant avec plus d'attention, on trouve que cette teinte n'est pas uniforme, et que le parenchyme du foie est formé, 1. par un tissu d'un blanc verdâtre, disposé sous forme de lignes ou de plaques irrégulières (c'est le tissu blanc ordinaire hypertrophie); 2. par un tissu d'un vert brun foncé, auquel dépend la couleur générale que présente le foie, et qui est l'analogue du tissu rouge ordinaire." This was a case of vitiated biliary secretion, with general biliary and partial sanguineous congestion. The ordinarily yellow substance was of a greenish white colour, being congested with greenish bile only; the ordinarily red substance was of a deep brownish green, this colour evidently resulting from biliary and sanguineous congestion combined. I have met with more than one case of this kind; I have also seen cases of jaundice in which there was no biliary congestion of the liver, and the highest state of biliary congestion without jaundice. In attempting to estimate the causes of the various shades of colour observed in the liver, it is not sufficient to examine the cystic bile alone; the hepatic bile should be also examined; and it will be generally found, as in the above case, that these shades of colour depend either on biliary or sanguineous congestion alone, or on the various combinations of both.

Sanguineous congestion of the liver is either general or partial. In general congestion the whole liver is of a red colour, but the central portions of the lobules are usually of a deeper hue than the marginal portions. Partial congestion is of two kinds, hepatic-venous and portal-venous congestion. Of the first kind there are two stages. In the first and most common stage, the hepatic veins, their intralobular branches, and the central portions of the plexuses, are congested. The congested substance is in small isolated patches of a red colour, and, occupying the centres of the lobules, it is medullary; the non-congested substance is of a yellowish white, yellow, or greenish colour, according to the quantity and quality of the bile it contains: it is continuous throughout the liver, and, forming the marginal portions of the lobules, is cortical. This is passive congestion of the liver; it is the usual and natural state of the organ after death, and probably arises from its double venous circulation. In the second stage, the congestion extends through the plexuses to those branches of the portal vein situated in the interlobular fissures, but not to those in

the spaces, which being larger than, and giving origin to, those in the fissures, are the last to be congested; when these vessels contain blood, the congestion is general, and the whole liver is red. In this second stage, the non-congested substance appears in isolated, circular, and ramous patches, in the centres of which the spaces and fissures are seen. This is active congestion of the liver; it very commonly attends disease of the heart, and acute disease of the lungs or pleuræ: the liver is larger than usual, in consequence of the quantity of blood it contains, and is frequently at the same time in a state of biliary congestion, which probably arises from the sanguineous congestion. Although in the first stage, the central portions of the plexuses, and in the second, the greater portion of each plexus, and those branches of the portal vein occupying the fissures, are congested, and although the plexuses are formed by the portal vein, yet, as this form of congestion commences in the hepatic veins, and extends towards the portal vein, and as it is necessary to distinguish this form from that commencing in the portal vein, the term of hepatic-venous congestion will not probably be deemed inapplicable to it. Portal-venous congestion is of very rare occurrence; I have seen it in children only. In this form, the congested substance never assumes the deep red colour which characterizes hepatic-venous congestion; the interlobular fissures and spaces, and the marginal portions of the lobules, are of a deeper colour than usual; the congested substance is continuous and cortical, the non-congested substance being medullary, and occupying the centres of the lobules. The second stage of hepatic-venous congestion, in which the congested substance appears, but is not, cortical, may be easily confounded with portal venous congestion.

The physiological deductions arising out of the preceding anatomical facts are extremely simple. If it could be shewn that two substances exist in the liver, it might be fairly presumed that this organ executes two functions; but each lobule being, in itself, a perfect gland, and of the same structure throughout, each lobule, and consequently the whole liver, executes but one function, the secretion of bile.

It has been shewn that all the vasa vasorum of the liver are branches of the hepatic artery and portal vein; that branches of the portal vein arise in the coats of the hepatic vein themselves; and that the veins of the coats of the vessels constitute the hepatic origin of the portal vein. The arterial blood having circulated through the coats of the vessels, becomes venous, and is conveyed by the veins arising in the coats of the vessels into those branches of

the portal vein which correspond to the vessels in the coats of which the veins arise; thus, from the coats of the vaginal ducts, veins, and arteries, they convey the blood into the vaginal veins; and from the coats of the interlobular ducts, veins, and arteries, into the interlobular veins. From the coats of the hepatic veins and inferior cava, the blood is conveyed into the interlobular portal veins. In the vaginal and interlobular veins, the blood conveyed from the coats of the vessels becomes mingled with the proper portal blood. This mixed blood is conveyed by the interlobular veins into the lobular venous plexuses, in which the lobular arteries probably terminate, after having nourished the secreting ducts. From the mixed blood circulating through the plexuses, the bile is secreted by the lobular or secreting biliary plexuses.

The blood which enters the liver by the hepatic artery fulfils three functions; it nourishes the liver; it supplies the excreting ducts with mucus; and, having performed these purposes, it becomes venous, enters the branches of the portal vein, and contributes to the secretion of the bile. The portal vein fulfils two functions; it conveys the blood from the artery, and the mixed blood to the coats of the secreting ducts. It has been called the *vena arteriosa*, because it ramifies like an artery, and conveys blood for secretion; but it is an arterial vein in another sense, being a vein to the hepatic artery, and an artery to the hepatic vein. The hepatic veins convey the blood from the lobular venous plexuses into the vena cava inferior.

Mr. Simon concluded from his interesting and ably conducted experiments, that the bile is secreted from the portal blood alone; and Mr. Phillips arrived at the same conclusion, from the issue of two experiments in which he tied the hepatic artery, the details of which are in the possession of the Royal Society. From the issue of three experiments in which the portal vein was tied, and in which bile was secreted, and from the cases related by Mr. Abernethy and Mr. Lawrence, Mr. Phillips concluded that bile might be secreted from arterial blood alone*. I have shewn that the bile is secreted from venous blood alone, this blood being composed of the two streams which enter the liver by the portal vein and hepatic artery; and from the anatomical details into which I have entered, it is evident that bile will be secreted, but in different quantity, whether the vein or the artery be tied, and from venous blood in both cases. The quantity of arterial blood conveyed to the liver is so small, and death so soon follows the ligation of the vein, that in experiments on

rabbits and kittens, in which I tied the vein, I cannot say that bile was secreted.

It appears to have been satisfactorily ascertained by Tiedemann and Gmelin, and by M. Voisin, that the bile is a purely excrementitious fluid, stimulating the intestinal canal, but having no influence on the formation of the chyle. The lungs separate from venous blood an excrementitious matter in a gaseous form; the liver, extracting from venous blood an excrementitious fluid, may be considered as the abdominal lung.

A few eminent physiologists, founding their opinion on false anatomical data, on the cases related by Mr. Abernethy and Mr. Lawrence, and on the absence of the hepatic-portal vein in the invertebrated animals, in which the liver is supplied with arterial blood only, maintain that the bile is secreted from arterial blood. Since the conclusions contained in this paper, respecting the physiology of the liver, were first submitted to the Society, I have been enabled, through the kindness of Mr. Stanley, to examine the liver of the child in which Mr. Abernethy found that the portal vein terminated in the inferior cava. Mr. Abernethy's account of the case is contained in the Philosophical Transactions for 1793. Mr. Green, in his anatomical lectures, had always described this case as presenting less anomaly than was commonly supposed. He considered that the umbilical vein ramified through the liver, that the artery probably terminated in it, and that the vein and not the artery conveyed the blood to the secreting part of the liver. Sir Charles Bell also, in speaking of this case, makes the following highly interesting observations:—"We may observe on this case, that it does not prove the bile to be, in the natural economy, secreted by the arteries and not by the vena portæ; for the artery here was unusually large, so that it performed a function in this instance which it does not usually perform. Had the artery been of the usual size, we might then have concluded that the vena portæ was distributed to the liver to serve some lesser use in the economy of the system, and that it did not secrete the bile. The liver, it is said, was of the ordinary size. Now as the bulk of the liver is, in its natural state, made up of the dilated veins, it is some proof of what I should imagine had taken place here, that by some provision of the vessels, the arterial blood had been diffused, and the celerity of its motion checked, previous to its ultimate distribution. Nay, it may have opened into the branches of veins answering to the extremities of the vena portæ. I conclude, that this singular and interesting case may strengthen the opinion which some have entertained, that the extreme branches of

e, e. The intralobular branches of the hepatic vein,

f, f. The uninjected central portions of the lobules.

No such view of the ducts as that represented in this figure can be obtained in the liver. The interlobular ducts are, in the figure, seen anastomosing with each other: I have never seen these anastomoses, but I have seen the anastomoses of the ducts in the left lateral ligament, and, from the results of experiments related in this paper, I believe the interlobular ducts anastomose. I have never injected the lobular biliary plexuses to the extent represented in the figure*.

Fig. 7. Representing the interlobular branches of the portal vein, the lobular venous plexuses, and the intralobular branches of the hepatic veins of three lobules.

- a, a, a. The interlobular veins contained in the spaces.
- b, b, b. The interlobular veins which occupy the fissures, and which, with the veins in the spaces, form venous circles around the lobules. This is the appearance which the venous circles present when examined with a common magnifying glass; they are, however, formed by numerous, and not by single branches, as represented in the figure.
- c, c, c. The lobular venous plexuses, the branches of which, communicating with each other by intermediate vessels, terminate in the intralobular vein. The circular and ovoid spaces, seen between the branches of the plexuses, are occupied by portions of the biliary plexuses, constituting the acini of Malpighi.
- d, d, d. The intralobular branches of the hepatic veins, in which the vessels of the plexuses terminate.

* See editorial note, next page.

the hepatic artery pour blood into the extremities of the vena portæ previous to this formation of the bile by these veins; but it still leaves us with the general conclusion, that the peculiarities in the distribution of the vena portæ are a provision for the secretion of the bile, and that the branch of the aortic system, the hepatic artery, is otherwise necessary to the support of the function of the liver."

I examined the liver of this child, which had not been examined by Mr. Abernethy, in the presence of Mr. Stanley, Mr. Mayo, and several other gentlemen, in the Museum of St. Bartholomew's Hospital. Mr. Abernethy had injected the arteries with red, and the hepatic veins with yellow size. As had been happily conjectured by Mr. Green and Sir Charles Bell, we found the open and uninjected ramifications of the umbilical vein (the hepatic-portal vein) accompanying, as usual, the branches of the hepatic artery and duct. By making sections of portal canals, we found the arteries, as Mr. Abernethy had described them, much larger than usual. In ordinary cases one principal artery is found in each canal; in this case two, and in some places three arteries, of equal calibre, were found in each canal. The branches of the umbilical, or portal vein, which are usually so much larger than those of the artery, were found, on the surfaces of sections of this liver, to be, as nearly as we could judge, equal in calibre to the united dimensions of the two or three arteries which accompanied each branch of the vein. Bichat, in support of his opinion that the bile is secreted from arterial blood, says, "*On dit que le volume du foie est considérable, à proportion de l'artère hépatique; cela est vrai; mais ce n'est pas un volume de ce viscère qu'il faut comparer celui de cette artère pour savoir si elle fournit les matériaux de la sécrétion, puisque nous avons vu qu'il est impossible que toute sa substance soit destinée à séparer la bile. C'est avec les conduits biliaires et leur réservoir qu'il faut établir la comparaison: or, cette artère est exactement proportionnée à ces conduits; il y a entre eux à-peu-près même rapport qu'entre la rénale et l'urètre; au contraire, les conduits biliaires sont bien manifestement disproportionnés à la veine porte.*" Bichat's opinion, and the argument here offered in support of it, are completely refuted by the dissection of the liver in this case. The branches of the duct were much smaller than those of the artery; in one canal, in which there were three arteries of equal dimensions, the duct was of about half the size of one artery. This case, therefore, does not establish an analogy between the biliary organs of the vertebrated and invertebrated animals; but, on the contrary, it shews

that the class of monstrosities to which it belongs forms a much slighter deviation from the ordinary vertebrated type than was imagined. Nor does it militate against the conclusions maintained in this paper upon the physiology of the liver; although, as Mr. Mayo observed, it cannot be supposed that the arterial blood, in its passage through the vasa vasorum into the branches of the umbilical vein, underwent the usual change into venous blood: and it was still, he contended, arterial blood, though less pure in character, which was conveyed through venous canals into the secreting part of the liver.

A case, similar to Mr. Abernethy's, which was met with by the late Mr. Wilson, is mentioned by Mr. Lawrence and Dr. Monro. The history of this case was lately read at a meeting at the College of Physicians, by Dr. Wilson, to whom I am indebted for the following particulars:—The subject was a girl, thirteen years of age, who met with her death from an injury of the head. The vena portæ terminated in the inferior cava; there were two splenic veins, one of which entered the portal vein, and the other the cava, near the point where it becomes surrounded by the liver. Mr. Wilson says, "*I could trace no vein passing into the liver at the cavity of the portæ; the remains of the umbilical vein were imperious; I traced them to the entrance of the portæ, and now regret that I had not traced them sufficiently far to see with what set of vessels they were united.* The hepatic artery," Mr. Wilson continues, "*came off in a distinct trunk from the aorta, and ran directly to the liver; it was much larger than it usually is, but not so large as the trunk of the vena portarum; it entered the liver as usual. The gall-bladder had nothing remarkable in its appearance; it was of a size proportioned to that of the liver, and contained more than half an ounce of bright yellow fluid, similar in appearance to the bile; it was not, however, submitted to any other test but that of sight.*" The umbilical vein in this case was obliterated as far as it was traced by Mr. Wilson; but, as in Mr. Abernethy's case, its hepatic branches were doubtless open, and received the blood from the artery, which they conveyed to the coats of the secreting ducts. No portion of the liver was preserved.

[As there appeared to us to be some ambiguity in the remark appended to the explanation of Fig. 6, we applied to Mr. Kiernan, from whom we learn that the engraving is intended to represent what his examinations have led him to believe is the ultimate arrangement of the parts, although he has not yet been able actually to demonstrate it. We have also been re-

quested to correct a mistake which occurred in the paper as published in the *Philosophical Transactions*; the portal vein being therein represented as conveying blood to the coats of the *excreting* ducts, instead of the *secreting* ducts (p. 392, line 30, of our present number). The following remarks we have considered of so much practical importance as to deserve a separate place in our columns: in the original it appears simply as a note.—ED. GAZ.]

METHOD OF INJECTING EMPLOYED BY
MR. KIERNAN.

I for some time experienced great difficulty in making successful injections of the minute vessels of the liver; and this difficulty, arising from the presence of blood in the vessels, was increased when my object was to inject the two veins in the same organ, no exit being then left for the blood. Very little advantage is gained by previously injecting warm water, a large portion of which remaining in the vessels dilutes the injection and obstructs its course. The object is to obtain a free passage for the injection through the minute vessels; this can be accomplished only by tying the portal vein and hepatic artery in the living animal, and thus depriving the liver of all its blood. In one minute after the application of the ligature, the liver becomes bloodless, and the sufferings of the animal may be abridged, and regurgitation into the hepatic veins prevented, by dividing the inferior cava near its termination in the right auricle. Before injecting, the body of the animal should be left in water during twenty-four hours, a ligature having been previously placed on the inferior cava above the diaphragm, to prevent the entrance of the water into the hepatic veins. If the liver be previously prepared in this manner, all the intralobular hepatic veins may be injected with one colour, and all the interlobular portal veins with another, and the course and distribution of each set of vessels may be studied with facility. The various appearances produced by congestion of the liver may be imitated by injection. This method of injecting is equally applicable to every other organ. I made a very successful injection of the portal and hepatic veins in the exsanguine liver of a man who died from the rupture of an aneurism of the abdominal aorta, under the care of Dr. Hope, in the Marylebone Infirmary. In the preparations of this liver, as in those made by injecting the vessels after the ligature of the portal vein and hepatic artery in living animals, the central portions of the lobules are coloured with blue, and the marginal portions with red injection.

EFFICACY OF THE VAPOUR BATH
IN CASES OF DIABETES.

To the Editor of the Medical Gazette.

SIR,

DR. LEFEVRE'S observations, published in the number of the *Gazette* for Dec. 6th, on the efficacy of the vapourbath in a case of diabetes, have brought to my recollection two instances of the same disease, in each of which I found the same remedy more useful than any other I had tried. If you think them worth publishing, they are at your service.—I remain, sir,

Your obedient servant,

THOS. WATSON, M.D.

Henrietta-Street, Cavendish Square,
Dec. 3, 1834.

Archibald Jameson, aged 40, a chair-maker, living in the New Road, was admitted into the Middlesex Hospital on the 23d November, 1830.

He stated that he made an excessive quantity of clear urine, having a pale straw colour, and a sweet taste. He complained of considerable thirst; loss of flesh; debility; a constant sense of weakness in his loins, and of fatigue and aching in his thighs and legs; a feeling of heat in the epigastrium, with uneasiness there after meals; disturbed rest; and unusual peevishness and lowness of spirits.

His skin was dry and harsh; his tongue moist, and nearly clean; his gums were vascular and spongy, and some of his teeth loose. His bowels costive; his appetite was good, but not voracious; his pulse 84, and somewhat sharp.

He gave the following history of his illness:—

In the month of March he began to wonder at the uncommon quantity of water he made. Before that time the secretion had been abundant, but this he had attributed to the usual influence of cold weather upon him. The month of March, however, being fine and mild, he was surprised that the quantity voided did not diminish; and he was subsequently convinced that the disease was *then* affecting him, if not sooner. By the end of April his strength was fast declining; and in the beginning of May he consulted a physician, who desired him to taste his urine: he found it

was sweet. He was under this physician's care for five weeks, and in that period had eight blisters on his loins, with much relief to pain which he had suffered there, took a mixture of iodine and arsenic, restricted himself in a great measure to animal food, and got much better. An accidental wetting by rain at this time was followed by a relapse. Subsequently a dispensary physician was consulted, who also advised animal diet, and prescribed pills, containing two grains of the sulphate of quinine, one grain of the sulphate of zinc, and one-third of a grain of opium, thrice a day. From this plan he again derived much benefit; his urine diminished in quantity, and became less sweet; and he regained strength. About a month before he came to the hospital, he once more caught cold, and all his symptoms returned in nearly their former severity.

He was a married man, with several children. Since June he had noticed a total loss of virility. He had no uneasiness in any part of the urethra.

At the time of his admission he passed thirteen pints of urine in the twenty-four hours, and was disturbed three or four times in the night by micturition. The urine was pale, and contained a large quantity of albumen; and effervesced after standing a few hours, in consequence of the commencement of fermentation. Its specific gravity was 1036. The quantity of fluid drunk daily was nine pints. His thirst was great, but less urgent than during the summer months, when it was so tormenting, and his mouth and tongue were so parched and clammy that he could not refrain from drinking; and in order to avoid drinking to excess, he was at that time in the habit of wandering into the fields, where no water could be got.

He stated also, as matters which had attracted his own notice, that warm drinks "ran through him" more quickly than cold, and that acidity of the stomach, by which he was previously much troubled, had entirely disappeared since his present illness began.

During the preceding winter he had been several times wet through, and had neglected to change his clothes.

On the 24th his bowels were moved by castor oil. He made thirteen pints and a half of water.

A hot air, or vapour bath, had just been constructed in the hospital, and it afforded, I thought, a good opportunity for trying whether the suspended functions of the skin might not be restored, and the perverted functions of the kidneys perhaps corrected, by that powerful mode of exciting perspiration. The patient was put upon full diet, consisting chiefly, but not entirely, of animal substances; and he took five grains of Dover's powder three times a day, and occasional aperients.

On the 25th November he went into the hot air bath, and after a short time perspired freely. He had a better night than usual; lost the sense of weariness and aching in his legs; and the next day made only ten pints and a half of urine.

On the 26th the quantity again rose to thirteen and a half pints.

He used the bath a second time on the 28th. A longer period elapsed before perspiration was established. He felt exhausted on coming out of the bath; but soon found himself more comfortable, lively, and strong, than before its use. Next day the skin was more natural; and, for the first time since his illness, he perspired spontaneously, though slightly; urine nine pints. On the night of December 1st he perspired in bed; urine eight pints and a half.

It would be both tedious and useless to pursue the case in all its detail: it is sufficient to state that the employment of the sudatorium was continued twice a-week for some time, and the Dover's powder given as before; that under this treatment a striking improvement took place, in respect both to his sensations and to the quantity and quality of the urine secreted; and that after a little time he began to gain flesh and weight. At one period the quantity of urine was reduced to four pints in the twenty-four hours. Its proportion to the fluids taken underwent a marked decrease, as will appear from the following comparison. During the first ten days of his residence in the hospital, the quantity of urine averaged ten pints and a half—the quantity of fluids drunk, eight pints and a half; *i. e.* the urine exceeded the drink by two pints.

For the last ten days, the urine averaged six pints and a half, and the drink eight; *i. e.* the drink exceeded the urine by a pint and a half. The

specific gravity of the urine varied between 1031 and 1039.

At his admission he weighed 111 lbs. On the 27th December his weight had diminished to 108 lbs.; it then began gradually to increase, till, on the 20th April, 1831, it had reached 120 lbs.

The following interesting statement, drawn up by himself, before he left the hospital, gives a very good account both of the symptoms which had most distressed him, and of the degree of relief he had experienced.

"The urine is reduced more than one half, and does not contain much sweetness, but sometimes tastes salt, with a mixture of bitter. My stools, which were dry, and like balls packed together, are now quite natural. The pains in my limbs are entirely removed. My spirits, which were very much depressed, are now revived, and cheerful. The unpleasant aching of my kidneys, of which I spoke little, lest I should be cupped in the loins, is now removed; only I feel weak there. I am cured of the pain in my stomach, and the circuitous working of the wind in my bowels, which formed lumps in my belly as it passed, resembling those formed by the cramp. I have likewise got rid of the palpitation at my breast, which was accompanied with a sort of dread. My breathing is much improved; perspiration in a great measure restored; and my skin, which was dry, is now become moist. I sleep well at night, whereas I could not sleep more than two or three hours out of the twenty-four. My thirst, which was excessive, has ceased to be troublesome."

He became an out-patient on the 8th of March, 1831, and left off the bath on the 14th. He told me that he was no longer impotent; and that he sweated naturally and easily. After a while he declared himself well, and ceased to attend.

I was sorry to see him among the applicants for admission on the 2d of the following December. His complaint had returned; but he spoke principally of new symptoms—symptoms which are well known to occur in diabetic patients, and which Dr. Prout had predicted in this case, from the qualities of the urine formerly described;—symptoms, I mean, of pulmonary phthisis.

He told us that he had remained well till the day of the coronation of his present Majesty, the 8th September.

On the evening of that day he took his children to see the display of fire-works in the Park, and got his feet wet. From that time he had cough. On the 1st of November he brought up, in successive mouthfuls, a pint of florid blood. The hæmoptysis continued, to a less extent, for some days, occurring two or three times a day.

He complained of some measiness on the right side of the chest, near the sternum. Percussion beneath the right collar-bone gave a dull sound, and pectoriloquy was distinctly audible in the same spot. The diabetic symptoms were not then severe, though they increased afterwards. He passed from four to five pints of urine daily; perspired occasionally; and did not suffer much from thirst. I now for the first time observed that his breath had a peculiar sweetish odour, much like that of an apple chamber.

I did not think it expedient to recur to the sudatorium; and instead of Dover's powder, I gave him a quarter of a grain of the acetate of morphia in solution every six hours. His case was now hopeless. On the 13th February, 1832, he was made, at his own request, an out-patient. On the 6th March he begged to be re-admitted; and on the 15th April he finally left the hospital.

I will insert here one or two further extracts from the hospital case-book, in illustration of the influence of certain ingesta upon the diabetic symptoms.

Throughout the greater part of his illness he had eaten with his meals a small quantity only of bread. Whenever this quantity was exceeded, though but a little, a sensible increase in the quantity and sweetness of the urine ensued. In March, 1832, being very uncomfortable, he abstained entirely from bread during two days, and, excepting one or two potatoes, from vegetable food of any kind. The quantity of urine fell immediately from ten to six pints; and from being very sweet, and clammy to the touch, it became (he said) bitter. His thirst almost ceased; he had much less aching in the limbs; and declared that he felt better than at any time during the preceding three months.

The acetate of morphia was gradually increased to half a grain every four hours. Twice, on his complaining of headache, drowsiness without sleep, and continual dreaming, I suspended this

medicine altogether. On each occasion its suspension was followed by a considerable increase of urine, great debility, and depression of spirits.

In the latter part of April 1832, his wife came to tell me he was much worse. I then saw him at his own house. He was breathing with difficulty, and in great distress. His tongue dry and parched, and of a brown-red colour. He died on the 30th, and the body was examined the next day. It exhaled an unpleasant mawkish odour, resembling that of his breath while alive.

In the upper part of the right lung was a cavity as big as a walnut; the rest of the lung was loaded with tubercles, and quite solid. There was a series of small cavities, all communicating with the bronchi, in the upper part of the left lung; they were filled with a slate-coloured matter. This lung was less diseased than the right; its lower lobe was tolerably free from tubercles.

The muscular parietes of the heart were flabby. The liver was pale and soft; perhaps enlarged. The kidneys were of a deep red colour without and within, but they had undergone no perceptible alteration of structure: Mr. Mayo, who saw them afterwards, thought them somewhat firmer than is usual.

The mucous membrane of the stomach and intestines was soft, but not remarkably vascular.

Wm. Patterson, aged 36, a wheelwright, admitted January 18, 1831. States that he voids from fourteen to sixteen pints of clear sweet urine in the twenty-four hours, and is obliged to rise four or five times in the night for that purpose. Complains of urgent thirst, pain in his loins, and aching in his limbs; constant dryness of the skin; occasional dimness of vision; and lassitude and inability to exert himself. There is a puffiness round his eyes, which makes him look as if he had been crying. Bowels habitually costive; tongue red, clean, somewhat glazed: it has been, he says, like a beef-steak, or like the pickled tongue of a bullock. Breath strongly saccharine; pulse 52.

Says that he has been ill twelve weeks; that the first change he noticed was the great quantity of water he made—more even than at present; that he has become progressively weaker and thinner;

that his appetite is good, and has been ravenous; both he and his wife wondered that he should be ill and feeble, seeing that he ate and drank so heartily; that he used to sweat naturally and easily, but has not done so at all since his disorder began, although he has tried to procure perspiration by going into a warm (water) bath; that the sexual inclination is much diminished, but he is not altogether impotent; that he has had some irritation about the orifice of the urethra, and at one time slight cough and some expectoration, both of which have nearly ceased.

His urine has the same sweet smell as is so distinctly perceptible in his breath. Its specific gravity is 1045. He had been taking opium pills, and some other unknown medicines.

Encouraged by the beneficial effect of the hot-air bath upon Jameson, I employed it in the same manner in this case also, and with the same good consequences. The patient was allowed one pound of meat daily, and a quart of milk. He took castor-oil and other aperients occasionally, and small quantities of opium, which was tried in various forms: the acetate of morphia answered better than any other.

The use of the sudatorium was followed by free perspiration, with immediate relief to his feelings; by a remarkable diminution in the quantity of urine, which became at the same time less sweet and of lower specific gravity; and, at length, by increase of strength and weight. After some time, it was found that perspiration occurred spontaneously, and then the bath was discontinued. The disease, however, though mitigated and rendered tolerable, was obviously not removed. I never observed the specific gravity of the urine to be less than 1038. The quantity was reduced, for a short period, to four pints and a half; but the usual average was nine pints daily.

He left the hospital on the 9th of May. Two or three weeks afterwards, his brother came to beg that I would visit him. He had got up, two days previously, saying that he felt unusually well: soon afterwards, he was attacked with acute pain in the epigastrium, nausea, and copious vomiting. He had drunk largely of strong ale the day before, and more moderately for several days preceding. When I saw him he was moribund; had pain in the abdo-

men, a small rapid pulse, and sunk features. He died the next day.

The stomach was large, of a purple colour externally, at its splenic extremity, and marked there with large veins. At the corresponding part within, there was a circumscribed red patch, as big as the palm of one's hand, and covered with mucus, which was tinged with blood.

The kidneys were large, and their cortical portion was paler and more easily torn than usual. The increase of bulk seemed to belong exclusively to that portion. Several large bony deposits, of irregular shape, were met with in the mesentery, occupying the place of mesenteric glands. These deposits consisted of phosphate of lime, with a little carbonate of lime and animal matter.

The lungs were perfectly sound in structure, but loaded with frothy fluid. The heart was large, pale, and soft. The pericardium rough and granular internally.

it is specially applicable has not been defined, nor are the occasional untoward consequences of the operation so familiar to medical men as it is desirable they should be*. If the various cases in which lithotripsy has been, or may be, performed, were detailed from the commencement to their termination, a series of facts of considerable practical value would be obtained; nor could the pages of our medical periodicals be more fitly occupied, than in furnishing the grounds for correctly estimating the value of an operation of such great importance.

A case of urinary calculus in which lithotripsy was performed, and which terminated fatally on the 12th day after the operation, has led to the preceding reflections; and, practically following them out, I feel it to be an imperative duty to detail the particulars of that case briefly, but explicitly, so as to enable practitioners, as far as I can, to form a correct judgment of the circumstances which induced the fatal result, and to estimate how far those circumstances affect the eligibility of the new operation.

UNSUCCESSFUL CASE OF LITHOTRITY.

To the Editor of the Medical Gazette.

SIR,

It may appear a trite observation to say, that in establishing the value of a newly-proposed remedy, or the comparative merits of different surgical operations, it is of the last importance that the unfavourable results, wherever such occur, should be as freely and impartially communicated to the profession, as those more fortunate events which appear to authorize a preference of the novel measures proposed. In no other manner can a just and permanent opinion of them be formed; and it is from the not infrequent violation of so obvious a rule, that remedies and operations at one time loudly commended, have, subsequently, from the disappointment of practitioners, been altogether, and perhaps unjustly, discarded.

The new operation of lithotripsy is one of those proceedings with which the medical public has not a very perfect acquaintance. No reasonable doubt can, I think, be entertained, that it is a decided simplification and improvement in practice; but the class of cases to which

September 8th, 1834.—Charles Elliott, æt. 64, a ribbon-weaver, of spare habit and pale complexion, applied to me for advice on account of severe pain in making water, followed by straining and prolapsus ani. The calls to evacuate the bladder occurred almost every hour during the day, and about every third hour during the night. The urine was rather high coloured, sometimes cloudy, and generally deposited a reddish sand.

He gave the following history of his symptoms:—About eleven months since he passed one or two small stones, about the size of half a pea, of a brick red colour. He had but little pain at the time, and none at all previously; in fact, he had before that been quite healthy, and subject to no complaint. About two months subsequently, after drinking beer with gin in it, he voided "black blood and water," as he expressed it, but without pain; and this hæmorrhage never recurred. From two to three months after the hæmorrhage, he began to have frequent calls to make water, accompanied with pain; and the

* "When a patient is cut for the stone, the operation puts life in danger; yet it is no protection against a return of the disease; and as often as it is repeated, so often does the patient risk his life. *Lithotripsy, on the contrary, does not endanger life.*"—*King's Lithotripsy and Lithotomy Compared*, p. 231.

urine was then thick, and had a gravelly deposit. The prolapsus ani commenced about three months since. Severe pain seizes him whilst making water; the flow of urine stops suddenly; then follow straining and prolapsus; and the prolapsus returns always with the pain.

His appetite is good; he has no thirst; the pulse is 75, regular, but rather weak; the tongue is moist, and but slightly furred; the bowels rather confined. He has no pain of the back, nor sickness, nor numbness of the thigh. His skin is never hot; he sleeps well, excepting that he is disturbed by the calls to empty the bladder. He was directed to take the caustic alkali, with mild aperients, and hyoscyamus at bedtime. These remedies afforded him some relief: but on the 22d he had a severe attack of dysenteric diarrhœa, a disease at that time prevalent in the neighbourhood. From this attack he was perfectly restored by the 29th, and was then sounded by Mr. Nankivell and Mr. Bicknell, who at once detected a stone. As the circumstances of the case appeared to us favourable for the operation of lithotrity, measures were immediately taken to obtain the valuable aid of Mr. Costello, who had very recently operated on a patient at Leamington. That gentleman promptly and most liberally proffered his services, and fixed the 17th of October for the operation. On that day, in the presence of between twenty and thirty medical gentlemen, Mr. Costello performed the operation with masterly skill and address. The stone was immediately detected and seized. The irritability of the bladder prevented the complete injection of that viscus, and much of the fluid was immediately and forcibly expelled. The stone appeared to be about an inch in diameter. It was seized and broken about seven times. A little blood escaped by the urethra during the operation, which occupied about 15 minutes. It was attended with but little pain. Some detritus came away with the instrument. The patient walked a distance of about three-quarters of a mile to the operation, and walked also about the room after it. He was conveyed home in a carriage, and had a warm-bath. On alighting from the carriage, so urgent was his desire to empty the bladder, that he made water before entering the house. Much sand, he said,

came away at that time, which, of course, was not collected.

For the first three days after the operation, no unfavourable symptoms appeared, excepting that he was obliged to pass his urine more frequently during the night—namely, almost every hour. Sand continued to come away, together with two or three large angular fragments; and the urine, which, during the whole day after the operation, was tinged with blood, became cloudy, depositing a whitish, opaque, muco-purulent fluid. On the 21st he complained of chilliness and general soreness, which he attributed to having taken cold. He had a white tongue; the skin rather hot, but moist; with thirst and loss of appetite. The pulse did not exceed 80. He experienced a constant "gnawing" sensation, as he termed it, at the neck of the bladder, with an almost incessant desire to pass urine. He did not call it pain, nor had he the least pain elsewhere. On the 22d, the pulse, still not exceeding 80, became irregular; his strength visibly declined, and his appetite became worse. All his uneasiness continued to be referred to the neck of the bladder, which was so constant, that, if he fell asleep for a few moments, it speedily awoke him; so that, in fact, he scarcely got any sleep. Sand was passed for the first three or four days, after which no more appeared, but the white opaque fluid deposit every day increased in quantity, and became decidedly puriform. About the 24th the pulse suddenly rose to 130, and became still more irregular; but the other symptoms did not vary in any important degree. The tongue continued white, and was somewhat drier; he had complete anorexia, but no sickness. The skin continued rather hot, and always covered with moisture. His mind was composed, and unaffected with delirium. On the 29th, the day of his death, he answered questions correctly, but muttered to himself at times, as indeed he had done for the last two or three days. Unless questioned, he made no complaint. The pulse was rapid, and intermitting. He took gruel, or whatever other fluid was offered to him, and remained free from sickness or hiccup. The bowels had not been moved for the last two days, and during that time the urine had partly escaped unconsciously; what was caught contained much puriform deposit,

and was rather offensive. His feet became cold, the breathing laborious, the lips blue, and he expired at six o'clock in the evening. During his illness, after the operation, he always replied cheerfully to the questions addressed to him, and anticipated that he should recover.

Post-mortem inspection.—The body was opened twenty-four hours after death, by Mr. Nankivell and Mr. Bicknell. The abdomen only was examined. The peritoneum was healthy, and there was no effusion into its cavity. The kidneys, ureters, and bladder, were removed in connexion. In removing the left kidney, which was felt to be enlarged, purulent fluid escaped, and the ureter of that side was seen to be thickened. The right kidney was first examined: externally it was of healthy appearance, and of normal size; and when divided, nothing morbid was at first observable. On pressing the papillæ, some turbid puriform fluid escaped; and on closer examination, two or three depôts of pus, each of them not larger than a hemp-seed, were detected in the cortical substance*. In other respects the kidney appeared quite healthy; there was no other sign of inflammation, and the ureter of that side was of natural size and appearance. The left kidney was enlarged perhaps to the extent of one-third of its original size, and purulent deposits were conspicuous on the external surface. On dividing the kidney, these collections of pus were found scattered through its substance, the intermediate portions having, however, a not unhealthy appearance. The pelvis was healthy, but purulent fluid could be easily expressed from the papillæ. The left ureter was thickened in its whole course, and in slitting it up, the lower third was found to be very vascular throughout the whole texture, and more thickened than the superior portion. Towards the termination of the ureter in the bladder, it contained a calculus, which weighed four grains and a half; and from the vascularity of that part of the ureter, it appeared probable that the calculus had been impacted there for some time. On opening the bladder, we were surprised to find the mucous coat exhibit a perfectly healthy appearance, being pale, without inequality or softness, and not

thickened. The cavity of the bladder was small; the muscular coat was hypertrophied generally. The substance of the prostate gland seemed rather vascular, but it was not enlarged. The bladder contained 10 fragments of calculus, but no sand or pus. These ten fragments weighed as follows:—

	Grains.
No. 1 (the largest) ..	110
2	40
3	20
4	10
5 to 10 inclusive .	15

195=3iii. gr. xv.

The gravel collected at the operation, and subsequently, amounted to 45 grains, including a few fragments, one of which weighed five grains. Of course some was lost, in particular on the first occasion of making water after the operation, when the man said a considerable quantity escaped, which was not collected. If the quantity lost in this way be estimated at 15 grains, which I believe to be a fair estimate, then the portion of stone removed by the operation amounted to about one fourth of the whole calculus. Had the patient survived for any length of time, it is probable that the smaller fragments would have escaped, as all of them, six in number, weighed only 15 grains, and, as has been already stated, one fragment weighing 5 grains had been expelled, and with scarcely any pain, for the man had a capacious urethra. With this allowance, however, three or four repetitions of the operation would have been required to relieve him of the whole calculus. The calculus appeared of light specific gravity, the figure flattened oval, the surface granular. It consisted of concentric laminae of a reddish or fawn colour, and was almost entirely soluble in caustic potash.

The circumstances which induced me to think that Elliott's case was a favourable one for lithotripsy were, his former good state of health, and the comparatively short period during which he had been afflicted with symptoms of urinary calculus: hence the probable small size of the stone, and the absence of any indication of organic disease either in the kidney or bladder; for up to the day of the operation his appetite and digestion were good, and he was free from fever. Notwithstanding, however, these negative

* See Andral's Pathological Anatomy, ii. 625.

signs, it can scarcely be doubted, from a review of the whole facts of the case, that structural disease of the left kidney must have pre-existed for some time; and it is to the morbid condition of that viscus, roused into greater activity by the operation, that the fatal termination of the case must, I conceive, be ascribed. The enlargement of that kidney, the dissemination of numerous depôts of purulent matter throughout its substance, and the general thickening and enlargement of the ureter of that side, were morbid phenomena, not very likely to have been so fully developed within ten or twelve days. It appears to me most probable, that from the period of the hæmorrhage in the early part of the complaint, structural disease had been very slowly progressing; so gradually, indeed, and with so little constitutional disturbance, that it was easily masked by the irritation constantly present in the bladder. It may be objected to this view, that if the increased irritation in the bladder, consequent on the operation, were powerful enough to excite fatal disease in the kidney, it would surely have occasioned disease in the mucous coat of the bladder. But it is chiefly because no disease of the mucous coat of the bladder was thus developed, that I presume the kidney must have been previously in a morbid state, for without such previous disease the irritation in the bladder would certainly seem to have been far more likely to induce structural disorganization in that viscus than in the remoter organ. However, the facts are impartially stated, and the reader can form his own inferences, if he deem mine erroneous.

It would be unreasonable to attempt to draw extensive general deductions from an isolated case. This much, however, I may be excused for saying—that too strict a scrutiny cannot be exercised in inquiring into the existence of organic disease in the urinary organs previous to the operation of lithotrity; and inasmuch as such organic diseases are less common in early life than in more advanced age, lithotrity will probably be attended with greater success in the young than in the old, as it certainly will be in the earlier periods of the disease whilst the calculus is small.

I am, sir,

Your obedient servant,

R. ARROWSMITH, M.D.

Coventry, December 19th, 1834.

SIR C. BELL'S DISCOVERY

OF THE

DECUSSATION OF THE POSTERIOR PYRAMIDS.

—

To the Editor of the Medical Gazette.

SIR,

IN a paper by Sir Charles Bell, published in the second part of the Philosophical Transactions for the present year, a statement is made, which, if it were true, would be not less curious than novel. Sir Charles Bell states that the inner and posterior fasciculi of the upper part of the spinal marrow partially decussate each other in a manner bearing some correspondence with the decussation at the origin of the *anterior* pyramids. The following are the words employed by Sir Charles:—"We may now survey the extent of the fourth ventricle. On each side of the calamus scriptorius are two pyramidal columns. To trace these upwards we must cut into the *iter ad tertium ventriculum* by dividing the *corpora quadrigemina*, and then we can trace them up into the *thalami nervorum opticorum*. By a section we may trace them into that body, and then diverging into the hemispheres of the cerebrum. Having followed these columns upwards, *we next trace them downwards, and find that they join, intermingle, and decussate, and again separate* and proceed down the spinal marrow*." Now to this point of anatomy I have repeatedly given my attention on former occasions, and I have again looked to it carefully since reading Sir Charles Bell's statement. I profess that I do not see, nor ever have seen, any thing like the decussation which he describes: I believe, therefore, that it does not exist: and as the point is one of great pathological interest, I take this opportunity of communicating to your medical readers the result of my observations upon it. I have always found the inner and posterior fasciculi of the spinal cord—those, namely, which approaching the fourth ventricle obtain the name of posterior pyramids—to be simply laid in apposition, and to be totally exempt from decussation.

Sir Charles Bell, as I gather from his essay, was led to observe this supposed decussation by wishing to find

* Phil. Trans., 1831, p. 476.

a channel, through which the crossing over of loss of sensation, in hemiplegia, to the opposite side of the body, might be supposed to take place,—resembling the channel for the passing over of muscular palsy, *for which alone* he thinks the decussation of the anterior pyramids would serve. He need not, however, have gone so far for such a channel. There is a point in the anatomy of the anterior pyramids with which he is evidently unacquainted, that accounts sufficiently for the pathological phenomenon. The lower terminal fasciculi of each of the anterior pyramids are not continued into the *anterior* fasciculi of the opposite half of the spinal marrow, *but plunge into its centre*, and therefore should be expected, *if they are the route of the decussation of symptoms*, to cause the loss of sensation in the parts supplied by the spinal nerves, no less than the loss of motion.

Sir Charles Bell, in plate xx. attached to the paper, fig. a, letters b, c, gives a representation of the decussation, in the existence of which I disbelieve.

In plate xix. a front view of the medulla oblongata and parts adjacent is given. The spinal accessory nerves are *represented* in it as arising from the anterior and lateral aspects of the spinal marrow: their real origins, are, however, from the posterior surface of the spinal marrow, and in this view the origins of both could not by possibility be seen.—I am, sir,

Your obedient servant,

HERBERT MAYO.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Elements of Materia Medica and Therapeutics; including the recent Discoveries and Analyses of Medicines.
By ANTHONY TODD THOMSON, M.D. F.R.S. and G.S., Professor of Materia Medica and Therapeutics, and of Medical Jurisprudence, in the University of London, Member of the Royal College of Physicians, &c. &c.

This book is not at all what it ought to be. The situation which the author holds, as lecturer in a great school, na-

turally led us to expect that we should find a work, professedly upon his own peculiar subject, superior to the crude productions which are merely got up for sale—more comprehensive in its views, and more accurate in its details. But in these particulars we find it very lamentably deficient; in fact, of the numerous manuals of *Materia Medica* which have of late years been published, it is decidedly the most incorrect which has fallen under our notice. This cannot fail to strike our readers as a very strong opinion to express; and it may at first sight appear to be a prejudiced one, when applied to a work on the same subject, and by the same author, as the *London Dispensatory*. We can only say, that we opened the volumes nothing doubting that we should have to bestow on them our hearty commendation; but the marks of haste and carelessness, to say nothing of doctrines positively erroneous, which crowded upon us, soon proved that our favourable anticipations had been misplaced. Upon reflecting on the cause of this anomaly—namely, that of the same author producing two books on the same subject, one good and the other bad, the only rational explanation which has suggested itself is, that the former was a mere compilation, in strict imitation—almost, or altogether, amounting to a copy—of the late Dr. Duncan's *Edinburgh Dispensatory*, which preceded it, while the latter is an original work, in which scientific arrangement and therapeutic reasoning are attempted,—and, as it appears to us, not always attempted with success.

In some respects, certainly, the design of the work is good, for we have no treatise on *materia medica* in the English language in which the object of classifying remedies, and explaining the *rationale* of their action, has been satisfactorily accomplished; for although Dr. Murray's arrangement may be regarded as upon the whole the best, yet is it very far from perfect; while his account of the medicinal agents is rendered every day more and more imperfect by the advances of medical science. Dr. Thomson's classification is compounded partly of Dr. Murray's and partly of Dr. Young's, the whole range of remedial means being reduced to vital, chemical, and mechanical agents—the only novelty consisting in certain omissions and certain alterations of position with respect to individual remedies. With these changes we have no fault to find, for in

truth we consider them very unimportant, looking principally to the account which is given of the history and operation of medicines, and but little to their mere place in the arrangement.

Keeping the volume on our table for reference, as occasion might require, we were much struck with the loose nature of the reasoning often adopted, and have been in the habit of making marginal notes at the moment:—of these we shall give a specimen or two, by way of illustration.

We find, at page 506 (vol. i.), that a smaller dose of opium is required in summer than in winter—a position which we do not dispute. But then comes the rationale. "Hecquet explains this influence of temperature by saying, that as heat favours the flow of sweat, the opium is carried off by it, and is thus prevented from materially affecting the brain: but Chavret, with more probability, supposes that, as copious sweating diminishes the mass of the circulating fluids, and renders the cerebral compression less powerful, the sweating may be regarded as a favourable crisis, which guarantees the brain from over compression. Both opinions are hypothetical: and it is more likely to depend on the greater irritability of the habit in summer than in the winter, and the consequent greater susceptibility of impression." Now here is a curious specimen of the author's logic: he states a proposition, for the proof of which two authorities are quoted—the which authorities go to prove *just the reverse* of what is intended; thus—Opium requires to be given in a smaller dose in warm weather; but Hecquet and Chavret maintain that increased perspiration carries off the opium, so that it affects the brain less in warm weather than in cold; therefore—what?—according to Dr. Thomson, because opium affects the brain less—therefore a smaller quantity is required to produce a given effect!

Again, it is intended to shew that the imagination has great influence over the operation of drugs; and to illustrate this the following anecdote is related:—

"A student who was labouring under fever, and was attended by Dr. Gregory, required the administration of an anodyne to procure sleep. He was informed by the Doctor that he would order an opiate for him to be taken at bed-time. The patient, however, from not hearing well, misunderstood the term, and supposed that he was to take

a purgative. Next morning, accordingly, when the Doctor visited his patient, he inquired what his anodyne had done for him? 'Anodyne,' replied the astonished patient, 'I understood it was a purgative, and a very active one it has proved. I have had four copious stools, and feel myself much relieved.' But we submit that this might with much more propriety have been regarded as resulting from some accidental cause, or have been adduced to exemplify the peculiarities of *idiosyncrasy*; and certainly the fact of opium occasionally purging is too well established to admit of its being attributable merely to the effect of imagination.

Connected with sedatives, we have some observations on blood-letting; and among others the following very extraordinary principle is laid down. Speaking of *active* hemorrhages, we are told—"during the flowing of the hemorrhage, although blood-letting be often resorted to, it is obviously unnecessary, as the hemorrhage will cease as soon as the quantity of blood lost brings down the plethoric state which induced it!" So that, according to Dr. Thomson, if we have a patient with a hot skin and a sharp pulse spitting up blood, we are to put the lancet in our pocket, and comfort ourselves with the very satisfactory assurance, that the bleeding from the lung "will cease as soon as the quantity of blood lost brings down the plethoric state which induced it." This passage will be found as above at page 467 of volume first, and requires no comment to shew its dangerous tendency—particularly in a work addressed to students.

Speaking of local depletions, the old story of making leeches draw blood *ad infinitum*, by cutting them across, is reiterated with the utmost gravity, and apparently with the most undoubting faith,—reminding us of Munchausen's horse, which was curtailed at the "nether bulk" while in the act of drinking, and would have drank on till this day had not the Baron luckily looked round, and seen that the water flowed out at one end as fast as it flowed in at the other! Not only, however, does our author never once doubt the fact, but he proceeds to explain to us that the dropping off of the leech, when gorged with blood, depends upon its respiration being interrupted; but when we "snip off their tails" they cannot

become so filled as to impede their breathing, and therefore they continue to suck. Now, unluckily for this doctrine, it happens that the leech will live for days immersed in oil; nay, it will live for an equal time in the vacuum of an air-pump: so much for the *explanation*. As to the rest, we can only admire the partiality of Dr. Thomson for an old wives' tale. Can he be ignorant of Cloquet's demonstration, utterly exploding the *false fact* of the sucking of leeches being perpetuated by their curtailment?

Taking just the opposite class of remedies, namely, stimulants, we have a considerable mass of information regarding them accumulated together, but in a form so crude and ill-arranged, as to make us lament the evident haste with which they have been thrown together. On the subject of wine we have some little display of learning, picked up from Dr. Henderson and other writers. Noah, we are told, was a husbandman, and planted a vineyard, "and he drank the wine, and was drunken;" on which Dr. Thomson makes the sagacious observation, that "to the present time the best wine is that of the grape," which, although very true as a fact, is, at least, rather singular as an inference from the scriptural narrative. The announcement, however, which follows is important—namely, that "cider, beer, and mead, are as much *wines* as that which is made from the grape." As this is the case, we advise the Doctor, next time he has any of the "Faculty of Physic" at dinner, to entertain them with a few bottles of *beer*: we doubt much if they will fall into the predicament of Noah, although, according to our author, they will have "as much wine" as he had. Another very queer assertion connected with spirituous stimulants is, that he says Galen recommended "BRANDY and water in small, but frequently-repeated doses, in diseased appetite." We should be exceedingly obliged to Dr. Thomson if he would favour us, in his next edition, with the original passage which he has thus rendered. And this leads us, *en passant*, to notice another questionable, or rather an unquestionably erroneous, opinion of the Doctor's, namely, that "wine should be taken *before* dinner, or at some period of the day when chymification is not in progress"—an opinion, he adds, which, "if it be correct as far as regards the healthy, is much more so as far as the dyspeptic

are concerned." Now we hold the fact to be just the reverse of this, namely, that many persons not usually troubled with dyspepsia have acidity and other unpleasant symptoms brought on every time they take a glass of wine *before* dinner, although they can take it during or *after* dinner with impunity; and that this is remarkably the case with those of delicate stomach, who, indeed, can very seldom bear wine in the forenoon without an aggravation of their sufferings.

The dose of some medicines is made unnecessarily small, and others are recommended to be given in quantities perilously large. Thus we are told (p. 714), in giving nitrate of silver, not to begin with more than one-sixth of a grain, which is only one-third of what the most cautious may prudently venture upon; and again, in "haemorrhagic affections" prussic acid is recommended in doses of ʒij .—*rapidly increased to ʒxij*.! Now we do not mean to say that ʒxij . of prussic acid may not have been given for a dose with impunity; but we are quite sure that, in a work addressed to beginners, it is imprudent to give such a range, or to use so loose an expression.

In other instances, no mention is made of important preparations of medicines in general use. Thus, we were desirous to see what opinion the learned Professor entertained of the acetic extract of colchicum, so frequently employed and so much recommended in the paper on Gout, published some years ago by Sir H. Hallford. What was our astonishment to find that no mention whatever was made of it, and that the author did not seem even aware of its existence!

But what shall we say of the account of sulphuric acid? We are told that this, "in its diluted state, consists of a fluid ounce and a half of the strong acid, and *four* fluid ounces and a half of distilled water; thence, each fluid drachm contains *ten* minims of the strong acid." Now, there are here two points to be noticed—1st, A mis-statement, and a serious one, putting the proportions as 1 to 3, when they ought to be of 1 to $\frac{9}{2}$; and, 2dly, a gross error. Even supposing that Dr. T. had stated *fourteen* instead of *four*, as the just proportion of water used in forming the London dilute acid, it is still *not the fact* that there are 10 minims of real acid in every drachm. But we think we know how the error has originated. Dr.

Thomson first made a blunder in his Dispensatory (see even the latest edition), where he says that there are 80 grains of real acid in every fluid ounce of dilute S. acid,—whereas the fact is, that there are but 48, or 10 per cent. In the Elements, however, the blunder is duly repeated in an improved form.

But it is in vain to descend to mere inaccuracies; for, though two lists of errata for the 1st volume appear, (viz. one in it, and another in the 2nd vol.) yet errors, almost without number, remain unnoticed, and sometimes it is difficult to suppose they rest altogether with the printer: thus *guaiacum* is incidentally mentioned several times in the first volume, and on each occasion (p. 70 and p. 109, *bis*, &c.) is spelt *guaiacum*; but it is fair to add, that in the second volume, where the drug is professedly treated of, it is spelt correctly. In page 98, we have *dycotyledons* for *dicotyledons*, and *carri* for *carui*; p. 117, *stramonium* for *stramonium*, and *hyosciamus* for *hyoscyamus*; we also find *menyanthis* for *menyanthes*; *anethemis* for *anethemis*; and *improthotonos* for *emprothotonos*. But, indeed, there is scarcely any instance in which a Greek word is given without an error: thus we find (p. 137) *κλωρος* for *χλωρος*; p. 420, *ξανός* for *κναρος*; and p. 527, two Greek words are fused into one, so as to make *υπνοτικονμηκωνιον* instead of *υπνοτικονμηκωνιον*. Neither is the Latin of the "Elements" much better: a quotation from Buchanan's History of Scotland is made to run as follows:—"Vis fructui radici ac maxime semini somnifera, et que in amentium si largius sumantur;" which we would defy Dr. Thomson or any other man to translate. But if we go on and take in the important word that follows in the original—"agat"—the case is altered. The Doctor, however, thinks its omission of no consequence, and leaves the reader to exercise his ingenuity by guessing at the meaning. Gregory is made to speak of "*scenæ novæ et amœnæ*," instead of "*scenæ novæ et amœnæ*;" and the classical Heberden fares little better, as he (p. 456, vol. ii.) has a most barbarous word put into his mouth: thus, "*radix hellebori nigri facultatum movendi menstrua sibi vindicavit*." Certainly these may be only typographical errors, but the circumstances under which they occur are—unfortunate.

Excepting the last quotation, we have limited ourselves exclusively to the first volume, and although we have by no

means exhausted our list, we are yet indisposed to proceed farther in so ungracious a task, much less have we either space or inclination to enter upon the second. Only one point more shall we refer to. It is not in the learned languages alone that mistakes occur; the English of our author is frequently, to say the least of it, very inelegant; as, however, we are not very fastidious in such matters, we should have made no remark on this head, but that we really cannot stomach the action of his emetics: they produce most wonderful effects: thus, "persons of torpid habits are more difficult to vomit by emetics than those of irritable habits;" the former, we suppose, clinging to the mucous membrane like dough—while the latter are more diffusible: and, again, "women in general are more readily vomited than men." We thought, when we last week published the history of Demetrius Stamatelli, who ejected a *fetus* from the stomach, that we were recording rather a remarkable event, but it is a mere trifle compared to vomiting *full-grown men and women*, in the manner described by Dr. Thomson.

To be serious, we must end as we began, by declaring that the work is not what it ought to have been; and as the second volume was published last year, and both have been puffed in some of the journals, we have no doubt of the first impression being now nearly sold, and a second edition preparing: we have therefore thought it a duty to the medical public to make such remarks as, we conceive, will induce the author, for his own sake, and for the sake of the institution with which he is connected, to have these same lectures (for such they obviously are) very carefully revised, ere they be again presented to the public.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* lueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

INQUEST IN A CASE OF CHILD-MURDER.

THE inquest held at Hornsey, in the course of the week, calls for a few re-

marks. The principal parties against whom a verdict of wilful murder has been returned are foreigners,—a M. Chabassier and his wife, who, having effected their purpose, have fled to the continent. Some of the particulars may be related.

On the 4th of October last, Mde. C. was delivered of an infant, full grown, and healthy. There was no want of due provision for the birth; but an attempt to pass the child off on the accoucheur as one of six months' having failed (the parties, we should observe, have been married only since April), a course of ill-treatment was systematically adopted towards the infant, under which it ultimately perished. With a view evidently to mystify the circumstances, the lodgings were changed two or three times during the month. The child was seen alive, but sickly, on the 25th of October; and on the 28th it was observed that Madame Chabassier and her attendant went out of doors, the latter carrying a bundle. From the evidence, we gather that they proceeded to the sexton of Hampstead parish, and easily negotiated with him for a coffin and burial for an infant which they represented as having been still-born. No bundle was noticed on their return; nor was the child any more seen alive. The Chabassiers quitted their residence two days afterwards, and it appears have since left the country.

In consequence of suspicions which were raised, and which led to active investigations on the part of the officers of police, the place of burial was at length discovered, and on the 9th of December the body of the infant was exhumed in Hampstead church-yard. On the day following it was examined medicolegally by Mr. Shaw, surgeon, of Hampstead, who noticed the state of decomposition of the body, and the appearance of an indentation round the neck. The infant, he considered, was

full-grown, and had lived from a fortnight to three weeks; but he could say nothing decisive as to the cause of the child's death. The contents of the stomach he would not undertake to analyse, but sent them for the purpose to the professor of *chemistry* (not of medical jurisprudence), in the Gower-street school.

At the adjourned inquest, a letter from the professor of chemistry, Dr. Turner, was read, in which it was stated that that gentleman had committed the task of analysing the contents of the stomach to *his assistant*, "who had been unable to obtain any certain indications of corrosive poison, such as vitriolic or oxalic acid, or of arsenic, as the quantity used would necessarily (?) have been so minute, that at that late period it would be impossible to decide. As to opium, the small quantity required to cause death in an infant would preclude his positively saying whether it had or had not been used."

After consulting together for an hour, the jury brought in their verdict of murder, grounded, we presume, altogether on the circumstantial evidence,—for nothing certainly was elicited either from the surgeon or the chemist's assistant to warrant such a conclusion. Were it not that we compared the reports given in different newspapers, in order to procure the most trustworthy account of the medical proceedings at the inquest, we should have rejected them wholly as apocryphal. But be the facts as they may, we cannot help adverting to the odd manner in which the negative toxicological testimony was obtained. First, the medico-legal referee—the parish surgeon, we suppose—called upon by the coroner to speak whether there was poison in the case or not, declines the weighty task; and with a modest, or at least a tacit admission of his incompetency, informs the jury that *he* (by what authority?)

had forwarded the matter found in the stomach to Dr. Turner. The Doctor takes care to save himself from any unnecessary trouble, throws the job into the hands of his assistant, and merely writes a letter, in which he says that nothing could be found. We will not stop to criticise Dr. Turner's note, of which we suppose we have the substance in the passage above quoted—a passage which contains no *chemical* information (all that was sought from the writer), and the toxicology of which is highly questionable—at all events, considerably irrelevant. The entire proceeding, however, shews in how very defective a state is the organization of legal medicine among us, and how anomalous the condition of our medical police; when a parish surgeon cannot apply the requisite tests for poison, but may, on his own responsibility, commit the investigation to a chemist, who devolves the duty upon his assistant, with whom the matter ends—in nothing.

Another gross defect in our system is exhibited in this case, by the transactions relative to the burial of the infant. It is left, it appears, wholly to the discretion of the sexton to bury all children said to be still-born, and that without any registry of the facts; there is no examination nor inquiry, especially if the applicants pay the necessary fees, and be respectable in their appearance (Mde. Chabassier, the sexton said, was “of very lady-like manners;”) in such circumstances a child above three weeks old may be readily passed off for one dead-born. With such a convenience as this at the parish church-yard, there can be no doubt but that child-strangling is far more frequent than is commonly supposed; the only wonder to us is that it is ever in any instance found out. In the present case we cannot help thinking, that had not the Chabassiers been foreigners, and gone awkwardly about the business, they might have escaped

even without suspicion. “There is no register kept of the burial of still born children,” said the Hampstead sexton in his evidence; “nor,” he should have added, “is there any inspection made of those so described.” We have often had occasion to allude to the gross irregularity with which the registration of burials in this country is conducted; each sect that has its own burying-ground keeping registers of its own, and there being no general registration of *deaths*: but any thing so lax as this permission, on the part of the parochial authorities, to bury new-born babes, or those announced as such, without comment or inquiry, was, we confess, far beyond our calculation.

The reason for omitting to register still-born children, if there be a reason for it, and could it be known, is, we suspect, rather an amusing one; our grave parish functionaries thinking, most probably, that a birth and a death occurring together neutralize each other, and ought not to be reckoned. Little are they aware (in this peculiarity, indeed, they have many to keep them in countenance among their more sagacious neighbours), that a note of the children still-born would prove both important and valuable in forming an estimate of the general mortality of the country. By an attention to the returns of this sort made in Flanders, M. Quetelet has been enabled to arrive at some conclusions highly interesting in a physiological as well as a statistical point of view. For example, he has ascertained that the number of the still-born throughout Belgium, is to that of other births, in the ratio of 1 to 31, and that the number of still-births in *towns* is double that which occurs in the country parts,—a conclusion which as nearly as possible agrees with the results obtained by Dr. Buck, at Hamburg. Nay, the *sexes* of the still-born are registered in the Belgic states; and from a comparison of these, it ap-

pears that the mortality among male fetuses is to that among female, as 3 to 2. Surely it is sufficient, even in the present humble condition of statistical research in this country, to mention these few instances, in order that the utility of such returns should be at once recognized and appreciated.

But to return, for we find we have rather diverged in our remarks from the point which at first induced us to take up this subject of child-murder. Our purpose, however, it will be perceived, was not so much to deplore the crime that has been committed, as to lament the imperfect means adopted for its detection—and the utter absence of measures such as might have operated towards its prevention. While such an imperfect state of things is permitted to subsist amongst us, we cannot but become more and more cautious every day to the perpetration of similar offences, for their frequency must divest them of the power of exciting surprise. Is there no remedy? We think that to a certain extent there is, in the plan that has been suggested—namely, the enlisting in the service of the state a class of well-qualified medical men, both in town and country, to act as competent referees on all medico-legal questions; not, as at present, leaving the coroner and his jury at the mercy of every chance candidate for notoriety, or, at best, of a class of practitioners whose limited education but scantily prepares them for such vitally important investigations. Even as we now write, an example presents itself to us which may serve to place in a stronger light what we say. The newspapers contain an account of an inquest, held only yesterday, in another case of infanticide. In proof of the mortal injury done to the child, the medical man who gave his evidence said he was *sure* the infant had come into the world alive, and had breathed—though

upon what grounds he was sure appeareth not: perhaps, however, the sort of proof which satisfied his mind may be guessed from the following singular question and answer:—

“CORONER.—Does not *the appearance of the blood* which has escaped since the *post-mortem* examination indicate the child to have been born alive?”

“MEDICAL WITNESS.—*Certainly; it is quite evident* the child was born alive!”

There is a specimen of the sort of evidence not unfrequently tendered and accepted at coroners' inquests, *even in the metropolis!* Need we add a word more to enforce the necessity of some new arrangement similar to that just proposed?

As to the propriety of establishing some better system of medical police and registration,—regarding that, we are less solicitous; for the matter will, we doubt not, find its remedy in no very remote session of parliament. The organization of the decennial censuses, so steadily conducted since the commencement of the present century, has already done much good, and will do much more by the practical example thus afforded of the value of statistical information. Add, moreover, the impulse given to such inquiries by the indefatigable philosophers of Belgium and France, and we cannot be too sanguine in expecting positive benefits to arise from this source at no very distant period.

PATHOLOGICAL LECTURES,

Delivered in King's College, London,

BY

PROFESSOR MAYO, F.R.S. &c.

Surgeon to the Middlesex Hospital.

VII.—On Diseases of Joints.—[Diarthroses.]

DIARTHROSES are those joints in which there is discontinuity. The ends of the bones articulated by diarthrosis are crusted with cartilage, and held together by a capsular ligament, a shut sac of synovial

membrane being reflected over, or lining, the articular cartilages and capsular membrane. The articular cavities of several of these joints are further deepened, or their shape somehow modified, by the introduction of a margin, or interposed plate, of fibro-cartilage. The tissues, therefore, which enter into the construction of diarthroses, are bone, cartilage, synovial membrane, ligament, fibro cartilage.

1. The habits of bone under disease have been already described; but it may be desirable that I should re-enumerate those affections of the osseous tissue, which are directly concerned in the diseases of joints.

The bones, or parts of bones, which go to form diarthroses, are the extremities of the cylindrical bones, the round bones of the wrist and instep, the articular processes of the vertebrae, the condyles of the occipital bone, and of the lower jaw, the scapulæ, ossa innominata, and heads of the ribs, with the edges of the dorsal vertebrae. The affections of these bones, in which the joints are implicated, are the following:—

a, Restorative action after fracture.

b, Atrophy.

c, Eburnation, or the solidifying into a texture like ivory. In connexion with joint diseases, this change occasionally supervenes in surfaces of bones from which the articular cartilage has been absorbed. The ends of bones which have become eburneous on their surface, are often enlarged; the eburnation, however, extends to no greater depth than from two to four or five lines. This ivory bone resembles exactly the dense osseous texture which forms the large and *malignant exostoses*.

d, Inflammation, producing as consequences—in the articular ends of the long bones, consolidation, and abscess, which may open into the neighbouring joint—in each of the kinds of bones specified, softening, with high vascularity of the surface of the bone in contact with the articular cartilage—in each kind again, softening, with gelatinous deposit in the cancelli.

e, Deposit of tuberculous matter in the cancelli.

2. The changes which have been observed in articular cartilages are the following:—

a, Cartilage is susceptible of reparation. In oblique fractures of the extremities of the long bones, and in the fractures of several other bones, the articular cartilages are broken, or ruptured. In a simple fracture thus extending into a diarthrosis, as the bone unites, so does the cartilage: the rent surfaces are found to adhere together by a layer of effused lymph; at the same time the sharp edge of the cartilage becomes a little rounded by absorption,

presenting an appearance not unlike the rounding which gradually supervenes of the sharp external edge of a fracture of a cranial bone. Whether the uniting medium finally becomes cartilaginous is unknown to me. The rounding of projecting edges, and deposit of lymph, are sometimes met with, constituting reparatory processes, after ulceration of cartilage has been arrested: the former occurring when the ulceration has removed a part of the thickness of the cartilage only; the latter, when the whole thickness has been removed. The same deposit of lymph is the medium of union in ankylosis, or when a joint becomes fixed after ulcerative disease. Ankylosis is osseous, cartilaginous, or mixed, according as the surfaces which are glued together are, both bone, or both cartilage, or one of each.

b, Cartilage is susceptible of two forms of softening; one I believe to be true atrophy. The appearance I allude to is often met with on the cartilage of the patella, in the bodies of persons a little advanced in years. The cartilage is softened, and seems split into soft thick villi. The change is accompanied both by partial absorption of the cartilage, and by a growth of the ends of the isolated villi in delicate shreddy productions, to which the synovial membrane probably contributes. This condition of cartilage deserves to be viewed, not as disease, but as natural degeneration of tissue.

c, The second form of softening is of rare occurrence; in it the cartilage becomes semi-transparent and gelatinous. In a case of severe inflammatory disease of the knee-joint, with caries of the articular surfaces of the bones, and inflammation of the synovial membrane, I found near the crucial ligaments, for the extent a sixpence would cover, the synovial aspect of the cartilage on the inner condyloid cavity of the tibia softened and semi-transparent, for two-thirds of its thickness.

d, Cartilage is susceptible of three varieties of ulcerative disease.

In the first, the cartilage disappears very rapidly, the absorption beginning upon the synovial aspect, leaving a surface perfectly healthy and smooth, either of cartilage or of bone. This change supervenes with great rapidity after compound dislocations, when the cavity of a joint remains exposed.

In the second, the process of absorption is slower, and produces an irregularly excavated and ulcerated surface, on the synovial aspect. This condition of cartilage is a very common element in chronic articular disease. I believe it to be generally, if not always, preceded by synovial inflammation.

In the third, the process of absorption

commences on the aspect of the cartilage towards the bone. I believe that this kind is essentially dependent upon inflammation of the articular aspect of the bone. The absorption takes place with two effects: either that of thinning the cartilage, leaving the synovial surface perfect; or else the cartilage becoming detached, by the absorption of the layer nearest the bone.

c, I am inclined to suppose that cartilage is susceptible of inflammation, or of some change analogous to it. In one preparation in our museum, injected vessels are seen to pass from the bone through the cartilage to its synovial aspect; and one of these distinctly anastomoses with a vessel on the inflamed synovial membrane covering the cartilage.

f, The gouty concretion, the principal ingredient of which is lithate of soda, is met with in cartilage.

3. Synovial membrane is liable to many changes.

a, It unites readily when torn or divided.

b, It is highly susceptible of inflammation. When inflamed, where it lines the capsular synovial membrane, or covers bone, it is liable to become thickened by an effusion of lymph upon its surface, resembling a growth of granulations,—at first soft and vascular, afterwards hard and gristly: where it is reflected over cartilage, it is liable to become slightly thickened, opaque, easily separable from the cartilage, elastic and brittle. I have once seen it for a small extent thickened, firm, white, and soft, on the patella, in connexion with sensible vascularity elsewhere on the patella and semi-lunar cartilages. The fluids found in inflamed synovial membranes, are, synovia scarcely changed, but in increased quantity—synovia thick, brown, and turbid—synovia blended with pus,—pus,—lymph.

c, The synovial membrane sometimes undergoes a very peculiar alteration of structure. Within its texture, or immediately without it, a growth of substance takes place, of a pulpy consistence, of a light brown colour, intersected by white membranous lines, and with red spots, formed by small vessels injected with their own blood. This formation, which attains a thickness of a quarter to half an inch, grows from any and every part of the membrane indifferently.

d, The synovial membrane is liable to be the seat of gouty concretion.

4. Ligament exhibits the following changes:—

a, It unites readily when divided or ruptured, the process being exactly analogous to that of the reparation of bone.

b, It is liable to atrophy. Through disuse ligaments become weaker, and are liable to become elongated.

c, Ligament is susceptible of inflammation. I cannot, indeed, say that I have seen, after death, inflamed ligament; but in rheumatism, gout, and syphilis, it is impossible to doubt the existence of inflammation of this tissue. In joints, of which the other tissues have been the seat of inflammation and ulceration, the ligaments are found softened, slightly transparent, and tear readily.

d, The gouty concretion is met with in ligament.

In taking a rough practical view of the pathology of joints, the following classification of the affections of synarthroses suggests itself: they may be arranged thus—First, consequences of injuries attended with more or less rupture, or laceration, of the constituents of a joint; secondly, inflammations affecting more than one joint, and depending upon a specific or general disturbance of the constitution; thirdly, inflammation of the synovial membrane of a joint, proceeding commonly from a slight and neglected injury, or cold, and leading to thickening of the membrane, and increased, and more or less altered, secretion of synovia; fourthly, acute inflammation, leading to suppuration in the joint, with ulceration of the synovial membrane; fifthly, inflammation of the synovial membrane, leading to acute ulceration of cartilage; sixthly, inflammation of the synovial membrane, not attended with thickening or effusion, but leading to slow excavated ulceration of the synovial aspect of the articular cartilage; seventhly, inflammation of the synovial membrane, with inflammation of the articular aspect of the bone, attended with ulceration of the cartilage upon both aspects, but principally upon that towards the bone; eighthly, ulceration of cartilage, with inflammation of the synovial membrane proceeding from serofulous inflammation or caries of the adjacent bone; ninthly, morbid growth of the synovial membrane; tenthly, foreign bodies in the joints.

a, The process of reparation after a strain, or partial rupture of the ligaments and synovial membrane, the integuments remaining entire, is simple and direct, supposing the part to be maintained in a state of quietude. Even when the synovial cavity of a joint is laid open, by a wound through the integuments, as in the extraction of loose cartilages, the process of reparation generally presents the same character—the wound of the integument uniting by adhesion. When a joint is opened, while the synovial membrane is

slightly inflamed, the restoration may be simple and direct. I saw, in consultation with Mr. Clayton, a gentleman 60 years of age, of a full habit, corpulent, asthmatic, who, fourteen days before, had fallen out of bed, and incurred a severe wound of the outside of the knee, from striking a chamber utensil, which was broken by his fall. The integuments, which had been cut through for the length of five inches, had been brought together by sticking-plaster, and the patient had been kept as still as an asthmatic cough and an irritable habit would allow. The synovial cavity had not been opened. In the course of a few days the joint became swollen, tender, and painful. On the thirteenth day, the wound of the integuments now granulating healthy, the granulations at the centre gave way; a gush of synovia took place from the joint, and the pain was relieved. The following day, the distention and the pain had returned. The point which had before given way was now opened with a probe, when the synovia again escaped: the pain was relieved. After this occasion, the joint did not require to be artificially opened; the synovia freely escaped, and continued to do so, lessening only in quantity, (but never altering in quality), for two months. The joint then ceased to discharge; and what remained of the original wound, closed. This patient is now able to walk about tolerably well, the joint being but slightly swollen, and weak. When a healthy joint is laid open, if it does not unite by adhesion, the consequences to be apprehended are inflammation of the synovial membrane, rapid disappearance of the cartilage; and even if the patient recovers, and preserves the limb, partial or complete ankylosis.

β. The inflammations of a constitutional character, which attack the joints, are of five kinds:—

1. After wounds, or surgical operations, an ataxic fever is often set up, which is attended with acute inflammation of one or more joints. In a young woman, seemingly in perfect health, a hardened subcutaneous lymphatic gland was situated above the breast, disconnected with it. It was cut out by Mr. Joberns. Great constitutional disturbance followed, which ended in the death of the patient, a few days after the operation. In her brief illness more than one joint swelled. I recollect accurately the appearance of one knee-joint: the synovial membrane was highly inflamed, and its cavity was filled with what looked like a mixture of synovia and pus.

2. In conjunction with rheumatic fever, several joints often become inflamed and

distended with fluid. This, it is probable, is commonly synovial only. In a case under Mr. Hawkins's care, in St. George's Hospital, a patient, *ætat.* 39, who had often suffered from rheumatism, died of inflammation of the pleuræ, sixteen weeks after a general rheumatic seizure of his joints from cold. "The synovial membrane of the right knee was full of a dark-coloured fluid, not purulent, but having the appearance of a thick synovia, tinged with blood. The synovial membrane was everywhere of a red colour, as if stained by this secretion; and the cartilages of the joint were similarly stained. There were small extravasations of blood in the cellular membrane, external to the joint."

3. I am not sufficiently acquainted with the pathology of gout to state what the tissues are to which it is confined in the inflammatory stage; but I conjecture that the synovial membrane is involved, with the other tissues, in this specific inflammation. At all events, the specific deposit, which is occasionally found in the cartilages, ligaments, bones, tendons, muscles, and ligaments, around gouty joints, is likewise found upon the free surface of the synovial membrane, and contained in its folds or fringes. Chalk stones, which attain a large size, are not mere earthy concretions; they have a kind of organization. A gentleman, between 40 and 50 years of age, was attended by Mr. Annandale and myself, for gouty concretions about several joints. One of the tumors was situated upon the back of the second joint of the ring finger, and proved particularly inconvenient, as our patient took pleasure in playing as an amateur on the violoncello. Upon this account, at his request, I removed the tumor by an operation. The operation was intensely painful. The mortar-like substance of the concretion did not form an unorganized mass below the skin, but was permeated every where by exquisitely sensible filamentous threads. The patient recovered, eventually, the use of his finger, but the wound was long in healing, the formation of the gouty deposit going on plentifully for several weeks after the operation, and filling the wound and exuding upon the dressings.

4. Inflammation of several joints frequently occurs in syphilitic cases. As far as I have seen, the synovial membrane is less affected than the other tissues in this disorder. The inflammation of the periosteum in syphilis shews how prone the fibrous tissues are to be attacked in this complaint.

5. Inflammation of the synovial membrane of joints is occasionally dependent on gonorrhœa. In this case the disorder sometimes bears a fixed and chronic cha-

raeter, and may be associated with ophthalmic inflammation. Sometimes the attack has the acute character, and is observed to occur upon the sudden disappearance or diminution of gonorrhœa. Often the inflammation leaves the joint first seized abruptly, and either transfers itself to another joint, or returns to the mucous membrane of the urethra.

7. Inflammation of a single joint from a neglected injury or cold, is least formidable when early attended with increased secretion of synovia, and even with thickening of the synovial membrane. The inflammatory disposition, finding this vent, does not produce more serious mischief. The following is an instance. Sarah Welsh, æt. 21, has now been nine months a patient in the Middlesex Hospital. Four years ago, after kneeling on a stone floor, the knee suddenly swelled, and became painful. She continued, however, to get about. At one time the pain and swelling would be greater, at another less. At the time of her admission, the knee was greatly distended, the synovial membrane sensibly thickened, the joint painful and weak; the pain aggravated on motion: there was no roughness of the articular surfaces. The knee is now reduced to nearly the size of the other, the fluid almost absorbed, the pain gone, her strength returned.

8. Acute inflammation of the synovial membrane leading to suppuration and ulceration of that membrane, is of extremely rare occurrence. Sir Benjamin Brodie narrates two such cases, of which the following is one:—

A child, nine years of age, fell, and wrenched her hip. In the evening she went to a dance, and while there, was seized with a rigor, followed by pain in the thigh and knee; she died a week after the accident. The hip-joint on the side injured contained about an ounce of dark-coloured pus; and the synovial membrane, where it was reflected over the neck of the femur, was destroyed by ulceration for about the extent of a shilling.

9. Acute inflammation of the synovial membrane, unrelieved by effusion into the joint, will sometimes excite a wonderfully rapid ulceration of the cartilage. Cases of this description are rare. As far as I have seen, their only favourable termination is in ankylosis. They are often attended with a suppuration in the cellular membrane adjacent to the joint. In one of the cases of this description which I have witnessed, and which alone I shall detail on the present occasion, several joints were simultaneously attacked. In two other cases, the attack commenced in one joint, and after a few hours took to another, in which it finally settled, leaving the first.

A boy, 11 years old, died in the Middlesex Hospital of hernia cerebri, three weeks after a fracture of the skull. He was perfectly well till the accident. Four days after its occurrence, a joint of one finger, and one ankle-joint, became swollen and stiff. The swellings suppurated, and were opened. On examining the parts after death, the abscesses were found to have no communication with the neighbouring joints; the joints contained no fluid or false membrane; the capsular synovial membrane was inflamed and thickened; the cartilages were partially absorbed, and in each joint with the same character. The cartilage of the under surface of the astragalus had become so thin as to be semi-transparent; the layer which remained was smooth, of the natural texture, and firmly adherent to the bone. The cartilage upon the tibial aspect of the astragalus was nearly wholly absorbed; patches only were left at the extremities of the upper and lateral edges, which were smooth, and firmly adherent to the bone. The exposed surface of the astragalus was healthy.

3. Sir Benjamin Brodie, in his masterly work upon joints, dwells particularly on the case of John Child, as exemplifying disease of the knee-joint *beginning with ulceration of the articular cartilage*. This patient, ætat. 33, in April 1814, was seized with a pain in one knee. This pain at first was slight, but gradually became severe. It was referred principally to the head of the tibia in each side of the ligament of the patellæ. *At the end of five months, the joint for the first time became swollen, and the swelling soon attained a considerable size.* It is unnecessary to quote the ease further than to state that the patient, under proper treatment, recovered.

This is one of a class of cases in which Sir Benjamin Brodie describes two stages—one of chronic ulcerative disease of cartilage, a second of more or less violent inflammation of the synovial membrane, with effusion of lymph and puriform fluid into the joint. It is my strong impression, however, that in all these cases there is an earlier stage; one, in which inflammation of the synovial membrane exists, which being unrelieved by effusion, or thickening of the membrane, vents itself in the ulcerative action which it excites in the adjacent cartilage. I will mention one striking case, which illustrates the view which I have adopted. Jane Dean, ætat. 17, was admitted into the Middlesex Hospital in June 1833. The preceding April the lower-outer, and anterior part of the left knee, became full and painful, which she attributed to cold, from kneeling upon the stones. Cupping, poultices, and a liniment, were used. The slight fulness went

away, but a pain which she had felt from the first, deep in the joint, now increased. The application of a blister mitigated the pain for a time; afterwards cupping twice repeated, leeches, and the use of a cold embrocation, had nearly removed it, when, upon using the joint in walking, the symptoms became aggravated. At her admission, but for a slight fulness to the outside of the patellar ligament, the knee had the appearance of being free from disease; but she was never without throbbing pain under the knee-pan, which was increased by motion or pressure. There was no mechanical impediment to perfect flexion or extension. From the period of her admission (the 18th June) to the 7th of February, when, after every remedy had been tried in vain, the limb was amputated, this patient, with one brief intermission, became progressively worse. The pain, during the last two months, was insupportable, and she obtained very short intervals of broken rest at night, through large doses of laudanum. The pain in the knee did not alter its place or character; but latterly, with the constant sense of throbbing, the patella felt as if lifted up. The leg wasted; the ankle and instep became œdematous. The slightest touch on the knee aggravated the suffering. Upon examining the amputated knee-joint, which was previously injected, the capsular synovial membrane was found highly vascular, but not thickened. Upon parts of the cartilage of the patella, of the inner condyle of the femur, and of the semilunar cartilages, the vessels of the synovial membrane were filled with the injection. Upon the patellar surface of the inner condyle, the cartilage was ulcerated, presenting some extent of irregular excavation. The synovial membrane adjacent to this, and, which is remarkable, covering a part of the ulcerated surface, was particularly injected. The texture of the cartilages of the joint was natural, and their adhesion to the bone perfect; but they had a slightly greenish tinge, which bore a remarkable contrast with the clear bluish whiteness of the cartilages of the ankle-joint.

The preceding case (attended, indeed, with very aggravated and unusual suffering) may serve to exemplify what I believe to be the ordinary course of ulcerative disease of the cartilage of joints: I suppose that inflammation of the synovial membrane first occurs, which, after an interval, is followed by ulceration of the articular cartilages on their synovial aspect; leading finally to increased synovial inflammation, to more extensive ulceration, to effusion of lymph and pus into the joint, and the formation of abscesses in its vicinity.

7. The following case well exemplifies the commencement of disease in inflammation of the articular aspect of the bones, as well as of the synovial membrane, leading to absorption of cartilage often on both aspects:—

F. D.—, ætat. 20, was admitted, November 30th, into the Middlesex Hospital. Three years previously, she had been attacked with pain and swelling of the left elbow-joint, which, being treated with leeches and embrocations, went away in nine months. Shortly after her recovery, the left knee began to swell at the lower and fore part: the swelling was attended with pain, which, although constant, was severe at times only; she thought it rheumatism. A year before her admission, the disorder in the knee became more serious; at times it confined her to her bed. The joint was hot, stiff, and painful. Several blisters were then applied in succession, and with some advantage. Other remedies were tried, but ineffectually. At the time of her admission, and for a month previously, she had been suffering the acutest pain, which the least pressure or motion aggravated to intolerable intensity. The knee was very slightly or hardly swollen; it was a little bent. There was no mechanical impediment to further flexion. Upon opening the knee-joint after amputation, a tea-spoonful of thin yellowish synovia escaped. The capsular synovial membrane was inflamed and thickened, and presented a jelly-like granulated surface, which extended a little way over the cartilages of the condyles. The cartilage was partially ulcerated on its synovial surface, on the femur, patella, and tibia. More serious disease was found at the junction of the cartilages and the bones. When the cartilages were cut through, either half of each could be easily torn from the bone. There were parts at which a discontinuity of substance appeared to have previously existed, the surface of the cartilage being slightly excavated, and the opposite surface of the bone ulcerated and extremely vascular. At other parts the cartilage did not come away clean, but tore off with it numerous granules of bone from the surface. This arose from the surface of the bone, for the depth of a line, having been highly inflamed and softened in its texture, so that it gave way to very slight force. Beyond the surface, the bone was perfectly healthy.

8. Ulceration of cartilage takes place secondarily in strumous disease of the bones. The practitioner is led to suspect this form of disease by the little pain and disturbance of the constitution which attends the slow swelling and progress of the articular disease, as well as by the general physical character of the patient. In the

lecture upon caries I have already adverted to this subject.

ζ. The morbid alteration of structure of the synovial membrane, of which I have already described the appearance, was originally observed by Sir Benjamin Brodie. Its progress is characterized by the filling up of the joint with a peculiar fleshy growth, which, without pain, simply impedes its motions. It is the tendency of this formation, after existing three or four years, to ulcerate; the ulceration spreads to the remaining articular tissues, and the joint becomes finally involved in the same general characters of destructive disease, which manifest themselves in the worst cases arising from inflammation, or from scrofulous affection of the bones.

κ. The loose bodies, which are found in joints, are of five different characters.

Sir Benjamin Brodie describes cases of inflammatory swellings of joints with effusion, on examining which a sensation is communicated to the hand, as if produced by a number of small loose substances, of a soft consistence, within the cavity of the joint, and just perceptible to the touch. He conjectures such loose substances to be portions of coagulated lymph which may have been effused on the inner surface of the synovial membrane, and afterwards have become detached.

What are termed loose cartilages, and have a texture which corresponds with the name, are growths that form immediately beneath the synovial membrane, where it either covers the bone or lines the capsular membrane. For a time they adhere by a pedicle, which is eventually ruptured by accidental force, or by the common motions of the joint. The inconvenience which they produce results from their moving freely in the articular cavity, and occasionally becoming wedged between the cartilages, causing intense and sickening pain.

The texture of detached bodies in a joint is sometimes bony, when they are formed in the manner described above. But Sir Benjamin Brodie mentions two cases in which the loose bodies being bony had a different origin. It occasionally happens, he remarks, that a bony ridge is formed, like a small exostosis, round the margin of the cartilages of the knee-joint. In the two cases alluded to, this preternatural growth of bone had taken place, and, in consequence of the motion of the parts upon each other, portions of it had been broken off, and lay loose in the cavity of the joint.

The capsular synovial membrane of a joint is sometimes covered with a growth of pendulous little bodies, resembling melon-seeds in appearance, but of various

sizes. This was the case in a patient between thirty and forty years of age, in whom I tied the external iliac artery for inguinal aneurism, and was afterwards compelled to tie the common iliac, upon secondary hæmorrhage supervening. The patient did not long survive the second operation. I was led to examine the knee-joints, observing that they were enlarged. Both were found to contain a little fluid. The capsular synovial membrane of each was covered with little pendulous bodies of different sizes, in their texture softer than cartilage. The patient had been used to walk about and take exercise; he was generally free from pain in the knees, but at times he had had attacks which were considered to be rheumatic gout.

Sir Benjamin Brodie describes a case in which he operated for the removal of a loose and moveable substance from the knee-joint: he found it, however, to be adherent; it was attached below the patella by a broad adhesion: this was divided, and the tumor extracted. The patient did well; and, notwithstanding severe inflammation which followed, the joint admitted of a considerable degree of flexion and extension. The tumor was two and a half inches in breadth, and somewhat less than half an inch in thickness at the thickest part; convex on one surface, and somewhat flattened on the other. It was of a firm fleshy structure. The general appearance of the tumor a good deal resembled that of the coagulum which is found in the sac of an aneurism; but it was not laminated; it had a smooth membranous surface, and it was manifestly organized, as vessels might be distinctly traced ramifying through its substance.

SMALL HOSPITALS.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to inform your anonymous correspondent, who signs himself "A Convert to Disinterested Opinion," that Dr. Elliotson, in his introductory clinical lecture at the London University, did not state "that it is only in a small hospital, containing from forty to eighty beds, that the student can hope to obtain any real knowledge of his profession." What he did state was, that a hospital containing from a hundred to a hundred and fifty beds was sufficient for the purposes of clinical instruction; that in large hospitals, the far greater number of cases could not be studied by the pupils, and that the most assi-

duous limited their attention to a certain number at a time—attending to the practice of but one, or at the utmost two, of the physicians and surgeons at once, and either never witnessing the practice of the rest, or taking it in succession. He did not say that small hospitals were superior, but equally good clinical schools; and I recollect he distinctly declared this advantage to exist in very large hospitals—that from the greater number of patients received, one instance, at least, of the most rare cases and operations was almost sure to be witnessed by the pupil during his attendance: and he moreover added, that he hoped to see the University Hospital much enlarged.

As to your anonymous correspondent's sarcastic allusion to Dr. Elliotson's disinterestedness, it is certain that Dr. Elliotson must have given up some hundreds a year in giving up St. Thomas's, and he officiates at our hospital for nothing.

I am, sir,

Your obedient servant,

GEORGE WRIDE.

University Library, Dec. 15, 1834.

[Mr. George Wride will find, if he turns to Dr. A. T. Thomson's published lecture, that he refers to what was said by Dr. Elliotson; and this, we presume, confirmed our correspondent in the belief of what he had heard. We are glad to be assured by Mr. Wride, that the learned Professor of Medicine "hopes to see the University Hospital much enlarged," because this shews that he agrees with us in thinking it at present "much" too small. As to the rest, gentlemen may write about it as they please, but it is quite notorious that the Professors of the London University praise small hospitals because they could not manage to get a large one; and that as to attending *gratuitously*, it amounts to this—they could not have had even their minimum of a hospital except by giving up the fees; by doing which, they calculate that if the thing goes on, the number of pupils attending their lectures may possibly be increased. It is a very good piece of worldly wisdom; but to call it disinterestedness, is—mere humbug.—*Ed. Gaz.*]

PHYSICIAN TO MARY-LE-BONE INFIRMARY.

THIS election took place yesterday; the following was the state of the poll at its close:—

Dr. Clendinning	12
Dr. Carsham	5
Dr. Marshall Hall	2

NEW MEDICAL WORKS.

LECTURES
ON THE
DISEASES OF THE CHEST,
In the course of which the Practice of
PERCUSSION AND AUSCULTATION
IS FULLY EXPLAINED,

Delivered at the London Hospital,

By THOS. DAVIES, M.D.

LECTURE XIII.

DISEASES OF THE PARENCHYMA-
TOUS STRUCTURE OF THE LUNGS.

ŒDEMA PULMONUM.

WE now arrive at the consideration of Œdema Pulmonum.

By œdema pulmonum we mean an infiltration of serum into the pulmonary texture. This disease was first noticed by Albertini, and was afterwards pretty fully described by Barrere, Physician to the Military Hospital at Perpignan, in his "Observations Anatomiques," published in 1753.

This affection has often been confounded with hydro thorax, but we shall hereafter shew you that by the latter term we mean an effusion of serum into the bag of the pleura, while this is an effusion of serum into the parenchymatous substance of the lung. Both may arise from the same cause, but this is the anatomical difference between them.

Morbid Anatomy.—In cutting into an œdematous lung, serum immediately flows from the section, the quantity varying very considerably, so that only a small portion may escape, or there may be a pint, or a quart, or even two quarts. This serum is usually colourless and transparent, but sometimes of a slight fawn colour; and according to the duration of the disease it is more or less spumous: thus, if the disease

be recent, the secretion is always mixed with a considerable quantity of air; if chronic, it contains scarcely any. The weight of the lung is increased, and it does not subside upon opening the chest. The lung still crepitates in the hand upon compression, because there is still a certain quantity of atmospheric air present. It also pits upon pressure, like an anasarcaous limb. You will sometimes find that the blood-vessels which supply the organ are almost exsanguineous; they are colourless, and nearly empty, and the lung itself is generally of a pale grey or yellowish tint.

The spongy texture of the viscus is never altered in this disease; it may always be seen after a certain quantity of serum has flowed from the incisions; but when the lung is entire, it is difficult to distinguish the air-cells, in consequence of the fluid which fills them diminishing their transparency. The increased secretion is evidently contained in the interlobular cellular tissue, as well as in the air-vessels.

If the œdema be recent, it is always, as I have already stated, very spumous, which I apprehend arises from the fluid hardly having had time to discharge or dislodge the atmospheric air contained in the cells. If the œdema be of long duration, you will find that the serum flowing from the section of the lung is not spumous; and I presume that this arises from its having had sufficient time to displace the air. A short period before death it would appear that a certain quantity of serum is deposited in the lung, except in cases of great marasmus; so that you will frequently find, on making a post-mortem examination, œdema of the lung, combined with sanguineous cadaveric deposit, and these deposits are always found in a position relative to that in which the body has been placed. Thus, if it be placed on the back, then they occur at the posterior part of the lungs; if on the face, at the anterior part; and if on the side, laterally;

shewing evidently that the position of these fluids depends merely upon their gravitation.

Symptoms.—*Functional Signs.*—Dyspnoea is a symptom of this disease, and as a general rule, its intensity is proportionate to the quantity of fluid contained in the air-cells. A slight cough often also occurs, followed by the expectoration of an aqueous fluid, more or less in quantity; sometimes, however, there is no excretion whatever; but if the œdema be combined, as it often is, with pituitous catarrh, then the expectoration increases considerably, and changes also in its appearance. It then consists of a colourless pituitous fluid, very similar to the white of an egg, mixed with an equal quantity of water: it contains also bubbles of air. If inflammation of the lungs supervenes, a few sputa may be seen of a slight fawn, green or rusty colour, but still transparent; and sometimes, from the co-existence of mucous catarrh, there will float upon the transparent pituitous secretion a certain quantity of yellow mucus, often assuming an irregular round form. General serous infiltration of the body frequently accompanies œdema pulmonum.

Local Signs.—Percussion rarely affords distinct signs of œdema pulmonum, inasmuch as the disease attacks usually both the lungs, and consequently there is no difference in the sounds which may be elicited from the opposite sides of the chest. In most cases the sound thus produced is tolerably good, because there is yet a considerable quantity of air contained in the air-cells; but in chronic cases, when the serum has displaced the air in the vesicles, the sound is duller on percussion.

Respiratory Murmur, &c.—You may readily suppose, gentlemen, that the respiratory murmur becomes indistinct, as the air cannot freely enter into the lungs. You will recollect that whenever air and serous fluid co-exist in the aerian cells, that the “rhonchus crepitans” is produced. It is therefore very distinct in this disease; the bullæ convey to the ear a sensation of humidity, and are larger than in peripneumonic engorgement.

As the local signs of œdema pulmonum and peripneumonia in its first stage, are the same, it becomes difficult occasionally to determine which disease it is; but inflammatory engorgement is almost always attended by fever, œdema rarely; engorgement is an acute disease, œdema most frequently a chronic one: the latter is commonly a symptomatic affection; the former an idiopathic. Yet it must be admitted that sometimes the diagnosis is attended with considerable difficulty, and requires great caution.

When the lung is also emphysematous, or when a severe dry catarrh supervenes,

the diagnosis becomes still more difficult, as the respiration is too slight to produce crepitation. By desiring the patient to inspire deeply, or to cough, you will often, nevertheless, hear the rhonchus crepitans.

Causes.—œdema pulmonum is very rarely indeed an idiopathic affection; it is almost always consequent upon some other disorder. First, it may arise where there is a general serous diathesis, in which the whole body is in a state of dropsy. Secondly, it may be consequent to certain fevers, more particularly of the eruptive class, and especially scarlatina. Thirdly, it frequently co-exists with measles and its catarrh. Fourthly, you recollect I mentioned that in the resolution of peripneumonia in the first stage, the red colour of the serum became absorbed, and the fluid which remains is colourless; the portion of the lung affected is then in a state of œdema. Fifthly, it accompanies chronic catarrh, more particularly the chronic pituitous form, and especially pertussis. Sixthly, and lastly, it arises from diseases of the heart.

These are nearly all the circumstances in which we find œdema pulmonum. Of all these causes it is most frequently the consequence of diseases of the heart, and then it may be considered as a dangerous symptom. I shall here endeavour to explain the general theory of dropsy arising from obstruction to the current of the circulation.

It must be well known to you, gentlemen, that the cellular tissue of the whole body, and the free surfaces of the serous membranes, are constantly bedewed with a secretion by means of which the organs move easily upon each other: this secretion is deposited by the arterial capillaries, and as the function is constantly acting, the fluid would accumulate, were it not for the absorption which is as constantly performing also: so that in the healthy state there is a perfect equilibrium between the quantity of serum secreted, and the quantity absorbed. That the function of secretion of the serum is effected by arterial capillaries, there can be no doubt. It is not doubted either, that the vessels, called absorbents, absorb; but it has been supposed that the venous capillaries perform the latter function also. To determine this point, Magendie made several experiments, and the one I am about to detail seemed confirmative of the latter opinion. The hinder limb of a tolerably large dog was amputated high up, and its separation rendered complete, with the exception of the femoral artery and vein, so that the limb hung suspended to the body by these vessels, the loose cellular substance around them being carefully dissected off. The upas, a most po-

tent poison, was then inserted under the skin of the amputated leg, and in a very short time its baneful effects became apparent in the body of the animal. Now the poison could only have entered into the general system by the femoral vein; for it would be inconsistent to suppose it could have ascended in the artery, since it would have gone against the current of the circulation. It was now objected that although the artery and vein might be clearly dissected of its surrounding loose cellular tissues, yet a sufficient number of absorbents might be left in the parietes of the vessels to admit the passage of the subtle poison. To answer this objection, Magendie, with great tact, after cutting off portions of the vein and artery, contrived so to introduce corresponding pieces of quills in their places that the blood flowed through them instead of the living vessels; yet the upas produced its effects in the same manner. This experiment seemed to be conclusive of the fact of the absorbing power of veins.

Lippi, of Florence, however, shewed that the lymphatics not only had a termination in the thoracic duct, but, as they followed the course of the veins, and were in close contact with them, they opened by minute orifices of communication into them, so that mercury injected into the lymphatics might be made to pass into these vessels; and I present you a preparation, in which mercury, injected into the lacteal absorbents, passed into the mesenteric veins; so that it is quite possible, in Magendie's experiment, that the poison first flowed into the absorbents, and from thence, by the minute orifices of communication, into the veins of the amputated portion of the limb, and that, consequently, the blood circulating through the isolated vein or the intermediate quill, was mixed with the poison before it had arrived at them. It is true that this demonstration does not disprove the absorbing functions of the veins, but it invalidates the experiments of Magendie, by shewing that they may be explained in another manner.

Under the supposition that either one or the other set of vessels absorb, or that they both do (for there is no inconsistency in the latter hypothesis), the following general proposition is not the less true: That any cause obstructing for some time the free current of the blood in the veins, will occasion an accumulation of serum in the parts from whence that blood is immediately derived. Thus it is a fact well known, that when the impregnated uterus enlarges to a certain extent, it often presses against the iliac vein or veins, and produces an enormous swelling of the corresponding limb or limbs: in this case the veins of the extremity affected become too

full, and they are often seen blue, meandering and varicose in consequence: no serum can now be absorbed, for there is no room for additional fluid in the veins, admitting that these vessels alone absorb. Admit, again, that Lippi's demonstration be fully proved, as I think it is, that the veins receive the serum by the minute orifices I have spoken of, still there is no room in the already-filled vessels to receive the lymph, and the lymphatics must become gorged also, and their function suspended. Finally, supposing that the lymphatic vessels alone absorb, we know that the parietes of the veins are so interlaced and interwoven by the absorbents, particularly the iliacs, that it is impossible to press upon the one system without pressing the other. I repeat again, that pressure upon the veins occasions dropsical effusion in the parts supplying them with blood, or, in other words, destroys the equilibrium between secretion and absorption in those parts.

Let us examine now how certain diseases of the heart produce dropsical effusions. You will soon perceive here that it is from obstruction to the venous circulation, although a small part of the arterial is involved in it also.

The aortic orifice is often obstructed, either by ossific or cartilaginous deposits in its valves, or by congenital malformation. Let us suppose the calibre of the aorta at its origin to be diminished one half: as the blood arrives at that orifice from the lungs in its ordinary quantity, and only half of the column can pass through it, it follows that that fluid must accumulate in the left ventricle, the parietes of which often increase in muscular thickness, and acts most energetically to overcome the resistance before it, or it dilates, or both these circumstances occur at once, the left ventricle being then said to be in a state of hypertrophy and dilatation. As the left auricle is a continuation of the ventricular cavity, it also becomes gorged with blood, and its parietes become thickened or dilated; the four pulmonary veins are filled also to their capillary extremities, and so far the arterial system is alone affected; but now the pulmonary arterial capillary vessels meet with their obstruction, in consequence of the fulness of the pulmonary veins; the pulmonary artery becomes gorged with blood, and as the right ventricle and auricle are continuations of the canal, they soon arrive at the same state of plethora. Thus in the whole round of the smaller or pulmonary circulation, a series of obstructions exist, the one consequent upon the other, and the result is, that the veins cannot take up the serum in the air-cells, or in the pleuritic cavity, nor can the lymphatics

ties, from the general plenitude of both sets of vessels; and œdema pulmonum, or hydro-thorax, or both, may be the consequence.

We will now trace the manner in which dropsy forms in the general cellular tissue. If the right side of the heart become loaded with blood, from the obstruction at the aortic orifice, the blood from the venæ cavae meets with its obstruction in the habitually overfilled cavities of the right auricle and ventricle. The superior cava swells; its branches, to their capillary extremities, become congested; the sinuses of the brain become turgid; the face and lips assume a leaden hue, and swell, and this swelling depends upon an accumulation of serum in the cellular tissue of the parts, arising from the obstructed state of the superior cava.

If the fulness of the superior cava produce these effects, where the propulsion onwards of the blood not only arises from the *vis-à-tergo*, but is also accelerated by the force of gravitation, a similar series of results must more certainly occur in the system of the lower cava, where that fluid has to mount by the mere vital force: abdominal dropsy, and general cellular serous effusion of the inferior extremities, then take place.

Treatment.—The treatment of œdema must depend upon the disease with which it is complicated. Thus, if it arise from a general serous diathesis, in all probability there is a disease of the heart, and this is the organ to which your attention must then be directed. If an organic lesion exist, palliative measures only can be adopted, the disease itself being generally incurable. In such circumstances, diuretics, mercury, and the occasional administration of elaterium, are useful. When it occurs at the termination of fever, except dyspnoea take place, there is but little danger, and it will generally give way to tonics, purgatives, and particularly to mercury. If it accompany measles and catarrh, the treatment will then merge into that adapted for these complaints. If it be the result of peripneumonia, it requires little or no treatment; if it be conjoined with pertussis, the treatment must be the same as described for that affection.

APOPLEXIA PULMONUM—OR HÆMOPTYSIS.

We now pass on to the affection called by Laennec *Apoplexia Pulmonum*, or that state of the lung which is the most frequent cause of hæmoptysis, or spitting of blood.

It is a singular fact that although this disease has been known from remote antiquity, although it is somewhat a common affection, yet its morbid anatomy has not been understood until lately; it has generally been supposed that hæmoptysis arises

from the bursting of large blood-vessels; but that is an erroneous opinion: it seems rather to depend upon an exudation of blood from the capillary vessels of the lungs.

Morbid Anatomy.—Laennec has given us the following description of the morbid anatomy of this disease.

The lung becomes as firm as in ordinary hepatization—I should say even much firmer. The disease is always partial, and rarely affects a large portion of the organ: its extent varies from a pin's point to three or four cubic inches: the firmness is most frequently exactly circumscribed, and the engorgement is as great at the circumference as at the centre: there is no gradual diminution of density, as in hepatization, but a distinct line of demarcation separates the healthy from the diseased parts: the surrounding cells are usually healthy and crepitant; they are often even paler than natural; sometimes they present a rosy or even red colour, depending upon the infiltration of a certain quantity of coloured serum.

The colour of the diseased part is of a deep black red, similar to that of a clot of venous blood, and differing from that of hepatization inasmuch as the former is homogeneous, and permits us no longer to distinguish the bronchial tubes, the blood-vessels, or interlobular cellular substance; for all are involved in a deep red colour. The neighbouring veins are often filled with concrete and half-dried blood. The lung, if torn, presents a granular appearance like hepatization, but the granules are larger.

The pulmonary tissue is less humid than in hepatization; you may scrape from the surface of a section a small quantity of black and half-coagulated blood; sometimes the centre of the apoplexy is softened, and filled with a clot of pure blood. It occasionally, though rarely, happens, that the substance of the lung may be torn by the sanguineous effusion; and Corvisart mentions an instance in which the pleura was lacerated, and the blood escaped into and filled its cavity.

Several apoplectic engorgements may occur in the same lung: often both lungs are simultaneously affected; and although they may be found in all parts of the organ, yet they are most frequently situated in the centre of the inferior lobes.

It is very easy to distinguish this disease from the ordinary cadaveric engorgement. In the latter case a red and spongy serum flows from the section, which fluid gravitates towards the lower part of the lung. The cedematous effusion is not circumscribed; there remain always some degree of crepitation; no granules can be seen, but the areolar texture of the

organ is to a certain degree apparent, and the lung may be rendered flaccid by repeated washings in water. A pulmonary apoplexy is always exactly circumscribed, very firm, of a blackish red colour, granulated, and scarcely humid, becomes but little paler by frequent ablations, and then does not lose its firmness.

Resolution may even take place in this morbid condition of the lung, for many persons recover. In the few cases which Laennec had seen, it appeared that the engorgement passed successively from a black to a pale red colour, and that it gradually lost its granulated texture and density.

[This demonstration was elucidated by a number of preparations, drawings, and diagrams.]

Signs—Functional and General.—The patient complains of dyspnoea, of oppression in the chest, and frequently of pains and heat along the course of the sternum. There is a frequent, short, and troublesome cough, depending partly upon the blood irritating the larynx as a foreign body, partly from the presence of that fluid in the trachea and bronchial tubes. The pulse is full, often hard, and presents a peculiar vibratory feel and quick movement, as if quicksilver were circulating in the arteries, constituting what is called the “*hæmorrhagic pulse*,” and is often accompanied by the “*bruit de soufflet*” of the heart and arteries. There is rarely fever, and the skin is of its natural temperature, or nearly so.

But the great and distinguishing symptom of apoplexia pulmonum is the expectoration of blood. It is usually copious, and returns frequently for some hours or even days, accompanied by a distressing cough, oppression in the chest, and great anxiety: the face is at first intensely red, but afterwards becomes pale; the extremities are cold. When the spitting of blood is abundant, the cough is often slight, and it would appear by the movements of the diaphragm to be ejected by vomiting—a circumstance which, no doubt, frequently takes place from some of the blood having been previously swallowed: this is further proved by the alvine evacuations being almost always of a very dark black red colour, as we find during an attack of hæmatemesis.

The colour of the blood expectorated is bright red, or black; it is spumous, and often coagulated; the quantity varies exceedingly; it is often enormous: Laennec speaks of an instance in which ten pounds were expectorated in forty-eight hours. I have seen two or three cases of similar quantities. These quantities are not, however, certain proofs of the magnitude of the apoplectic engorgement, as the bron-

chial mucous surfaces sometimes, though very rarely, give origin to great hæmoptyses, and large apoplexies do not always give rise to great hæmorrhages; nay, it sometimes happens that an engorgement of one or two inches may exist without producing any expectoration of blood.

Local Signs.—From having seen in two or three instances the expectoration of blood increased by an injudicious mode of examining the chest, particularly by obliging the patient to inspire deeply for the purpose of hearing the sounds more distinctly, I rarely now make any local observations, except I can do so without occasioning the patient the slightest fatigue or change of position. A local examination is also less necessary, because the general and functional signs are upon the whole sufficiently evident to indicate, if not the seat, at least the nature of the affection, and the treatment required. But these signs are as follow:—

Percussion indicates but little, inasmuch as the apoplexy is usually but of slight extent, and is so placed towards the centre and base of the lung that no difference of sound can be appreciated: if, however, the engorgement be considerable, and approach the surface, then percussion would elicit a dull sound from the part of the chest corresponding to the part of the lung affected.

Auscultation affords two signs: the first is absence of the respiratory murmur, proportioned to the extent of the apoplexy: the second is a “*rhonchus crepitans*,” surrounding the part where the murmur is inaudible, indicating the presence of slight rosy serum around the engorgement: this crepitation is heard at the beginning of the disease, and afterwards ceases. When these signs occur, it is evident that the hæmorrhagy has its source in the substance of the lung, and not in the bronchial tubes; but as, in bronchial hæmorrhagy, a mucous rattle, formed of bullæ with apparently thin parietes, and seeming to burst from distortion, is audible, particularly at the parts of the chest corresponding to the roots of the lungs, this species of rhonchus is doubtless produced by the presence of blood in the large bronchial tubes.

Causes.—The causes of apoplexia pulmonum are the same as those of bronchial hæmorrhagy; as, general plethora, the abuse of alcoholic fluids, singing, playing on wind instruments, violent exercise, blows upon the chest; in fact, any cause tending to accelerate the circulation.

A pulmonary hæmorrhagy may be vicarious of some other habitual discharge of blood; thus the suppression of the hæmorrhoidal flux has been said to produce hæmoptoe. The cessation of the catamenia

at the critical period of female life is certainly an occasional cause of this disease, and a surprising quantity of blood is sometimes lost from the lungs at this period, and yet the patients usually recover. I have also seen hæmoptoe co-exist with amenorrhœa.

Laennec observes that spitting of blood often occurs during the primary eruption of tubercles: it appears to me that that sign is most common at the time of their softening. The quantity is usually then inconsiderable; generally merely a few spots or streaks mixed with the sputa. It might be supposed that the destruction of portions of the lung consequent upon the softening of tubercles, and the formation of excavations, would produce considerable hæmorrhagy: I have seen such cases, but they are very rare; for, as we shall hereafter find, the blood-vessels, as they approach tubercular cavities, become obliterated.

Temperature has evidently an effect in the production of this affection: thus the sudden or long-continued impression of cold acts as a cause. Laennec conceived it possible, from seeing such immense quantities of blood occasionally ejected, that there must occur a sudden dilatation of that fluid. It is certain, when the atmospheric pressure upon the body is diminished, as in ascending high elevations, dilatation takes place, as the surface of the body then becomes turgid, and considerably reddened by the fulness of the capillaries, and effusions of blood from the nose, mouth, and bronchial surfaces, often happen. You will observe also, that when the heat is great and of long continuance, hæmoptysis is most common, as in the months of July and August.

Obstructions at the aortic or mitral orifices, by inducing sanguineous engorgement in the pulmonary circulation, may produce apoplexia pulmonum. These are, indeed, among the most common causes; but we shall advert to them again when we arrive at the description of disease of the heart.

A sudden and fatal hæmoptoe is sometimes caused by the rupture of an aneurism into the trachea or its pulmonary divisions. I present you specimens of these lesions.

Treatment.—As, in the ordinary forms of hæmoptysis, the pulse is strong, full, and jerking, so it becomes necessary to diminish the force of the circulation by abstraction of blood. Venesection is the best means of effecting this, and the quantity to be drawn should be proportionate to the force of the individuals, and to the fulness, tension, and jerking of the artery. I never consider the patient safe until this violent action of the pulse is subdued, or at least very much diminished. A large bleeding

effected at once is better than a number of small bleedings. Cupping, or leeches, in some cases may be employed, when the patient's powers do not admit of general depletion.

The next point to be attended to, is to insist upon the most positive repose, both of limbs and voice; do not allow your patient to speak, put your questions in such a manner that he may answer you affirmatively or negatively, by gestures alone, recollecting that to speak it is necessary to throw the lungs into increased movement, and they should be as quiescent as possible.

You should allow a free current of cold air to pass over your patient; let him be but very lightly covered; wash the chest and neck frequently with cold water, or vinegar and water, or, what is better still, apply, from time to time, a large bladder containing a quantity of pounded ice, to the surface. Let the thirst be satisfied with cold fluids, avoiding of course all stimulants.

After having bled your patient, and placed him under the circumstances I have detailed, then you will find the administration of a drastic purgative to be useful: it was the practice of Sydenham, and it tends considerably to diminish the force of the circulation.

I confess I have not much confidence in other remedies in this disease: you will find that amongst them the digitalis is the best; alum, the acids, and the superacetate of lead, are commonly given, and you may use them according to the formula you will find in medical works. Dr. Rush, of Philadelphia, recommended large doses of common salt.

When the force of the pulse is diminished, and the violence of the disease is abated, counter-irritants applied to the chest, as dry cupping, stimulant embrocations or blisters, are most useful means of relieving any remaining oppression or dyspnoea.

You will occasionally find, in persons of debilitated constitutions, the hæmorrhagy to be of a passive kind, that is, the quantity of blood expectorated is, upon the average, small, the pulse weak, although frequent, with no jerking or fulness. In such cases, general bleeding cannot be borne; you must depend upon repose, upon the application of external stimulants, and upon the use of the acids and astringents I have already mentioned.

A teacher, gentlemen, is obliged to select for his subjects marked cases, so as to give good exemplary ideas. In describing this disease, I have taken two extreme instances; the one accompanied by increased tone of the system, the other by diminished power; but there are also all shades

of intermediate differences, requiring modifications of treatment, which neither my time nor your patience will permit me to detail; but the knowledge of which is to be acquired only by a sedulous attention to practical or, as it is called, clinical medicine.

CLINICAL LECTURE
ON
CANCER, MORE ESPECIALLY ON
CARCINOMA OF THE MAMMA,

Delivered at the Middlesex Hospital, October 18, 1834,

BY SIR CHARLES BELL.

THE surgeons of this hospital are bound, after the example of the founders of the cancer-wards, to pay every attention to this important class of diseases. At present there are unusually few cases of cancer in the house, for there is perhaps not a month in the year in which we have not a great many more; and yet there are sufficient to mark the importance of the subject, and to excite your sympathy in the highest degree. There are cases before you sufficient to shew, that, whether you shall hereafter be physicians, surgeons, or accoucheurs, if you have practice at all, you are sure to encounter a great deal of responsibility on this subject, and you will be uncommonly fortunate, or callous, if you do not experience pain and trouble.

No wonder that authors have acknowledged their incapacity to define cancer, and their inability to treat it methodically; for the term *cancer* is a vulgar word; in common language it means a malignant ulcer which cannot be healed—which goes on progressively to the destruction of the patient; and a great many diseases must, of course, be spoken of under such a term as this. But the word we ought to employ is *carcinoma*, and the disease to which I shall first direct your attention is the carcinomatous tumor of the mamma, in women of a certain age. Gentlemen, I entreat your attention, for I am aware that what I have to say will little interest you unless you have a forecast of the very distressing questions you will have to determine on, and unless you consider the matter in a manly and rational way.

The term *scirrhus* is principally employed by the authors you study on this disease. Now *scirrhus* properly means only those hard tumors which may arise from a great variety of different causes, local as well as

constitutional, and which hardness results from morbid interstitial deposits. Certainly, in some authors, you find the term *exquisite scirrhus*, by which they mean that hard lump which will, in process of time, form an open sore—a true cancer. I believe, then, I cannot be better employed than in explaining what *scirrhus* means, and how it may arise. Properly it means, then, only a hardening; and it may be by an interstitial deposit, a consequence merely of a slow increased action, or it may be attended with a peculiarity of action—that is to say, it may arise from partial and accidental irritation, or it may be constitutional.

To illustrate this, we shall take the testicle, as affording something like a fair parallel with the gland which is principally to engage our attention. You are aware that the testicle will swell with phlegmonous action, under the influence of inflammation in the urethra, occasioned usually by gonorrhœa—sometimes by the improper use of a bougie or catheter, or even in consequence of the operation of lithotomy. The effect of this inflammation will be a swelling, which, when it subsides, leaves a hardness, or scirrhus; and I beg of you to notice a man in Stafford's ward, named Charnell, where you will find just such a scirrhus of the testicle.

Finding the gland thus enlarged and hard, it becomes a question whether this be the effect of mere common irritation, and consequent common inflammation, or whether it be irritation influenced by the constitution. The same irritation will produce, in a young man, a scrofulous testicle, and in an elderly person a scirrhus threatening cancer. The question how far the swelling is constitutional, enters into every consultation on such a case, and of course whether the swelling, being a consequence of mere irritation, is to be removed by subduing the inflammation, or whether we must not remove also the constitutional peculiarity. If a blow be inflicted on a bone, a very natural consequence of that would be a swelling, and sometimes a tumor or exostosis will arise from it; but if the person be labouring under syphilis, the tumor will not subside under depletion, leeching, fomentations, and so forth, because, although the vascular action which is in excess be removed, yet the influence of the constitutional peculiarity continues. In the same way, if a youth who is strumous, with a strong scrofulous condition, receives a blow, the effect is not merely such as would be produced in a healthy person—mere inflammation of the part, and swelling—but there is mixed up with it the

constitutional peculiarity, and you have to subdue the overaction, and at the same time support the constitution, or use those remedies which you know are good in a strumous habit. This I take merely as an illustration, and you will find the use of it as we proceed to our proper subject.

Do not be surprised at the volume of papers in my hands: these are the records of my observations on the subject, which, as surgeons of the cancer institution, we are bound to keep, and to lay before the board. I am using them as furnishing us with the best examples drawn from twenty years' experience.

The first general head to which I beg you to attend is this:—

OF THE PERIOD OF LIFE AT WHICH CARCINOMA APPEARS IN A WOMAN, AND THE MANAGEMENT OF THE FEMALE CONSTITUTION WHEN THREATENED WITH SCIRRHOSITY AND GLANDULAR ENLARGEMENT.

I am of opinion there is a family peculiarity of constitution connected with carcinoma. A woman in whose family scirrhosis has appeared, ought to be more than usually cautious in attending to her health, and to the influence of the uterine change upon her constitution as she advances in life.

Secondly, there is, in my mind, a strong alliance between scrofula and cancer; so that in a family in which struma is inherited, there ought to be especial attention paid to the women of that family at the change of life—by which we mean when menstruation ceases.

Carcinoma, like some other diseases, is too apt to prevail in the descendants of such as have suffered from the disease. A person will come to you with paralysis, saying that his father suffered from this disease at the period of life in which he now presents himself; and the same is the case even with dropsy: a person will come and say, "my relatives have suffered from this complaint." So will a woman with a tumor which threatens to be carcinoma, come to you and say, "I am anxious about this; it makes me unhappy, because my mother and my aunt suffered from what I am now threatened with."

Thirdly, The age at which the disease prevails, is from 40 to 55; and it is more acute, runs a more rapid course, at 45, than from 55 to 65, or 70. It is very important for you to notice this. A woman presents herself to you as a patient, with a hardness in the breast threatening carcinoma. The disease will run more rapidly if she is only 38, or 40, than if she be decidedly an old woman. For example: there is an old woman, a patient of mine,

in the cancer ward, with an enormous carcinomatous tumor, now extending over all the side. She is very old; but if she had been 40, these horrid tubercles would have burst into open cancer, and she would have died long since; whereas she has seen that ward filled and emptied many times, and now remains in a tolerable condition of health.

5thly. In men, as well as in females, we observe a climacteric period; and it is well to notice what takes place at this period of life, exclusive, I may say, of the uterine system, which claims such importance in the other sex. That condition, then, is marked by a gradual decay of strength, a listlessness of mind, an incapacity for business, and sometimes great depression of spirits. The secretions are disordered; and irregular slow fever affects him; there is thirst, but no want of appetite; and there is increased action of the kidneys. At such a time, the mind should be supported by friendly and social discourse, travelling, and change of scene; the digestion should be watched, and exercise enforced. But if, instead of this, when these symptoms prevail, some family misfortune or real cause of distress should unhappily befall him, ten to one but he will not be able to bear up against it: some organic disorder will begin to shew itself, with a certain indefinite change in the countenance and general expression. Happily, however, this condition of the general system very often passes off, and vigorous health is again established.

6thly. By this digression I mean to infer, that in women the change of constitution may not at all times depend upon the uterine influence, but may have a source more akin to what takes place in the other sex: yet I must affirm, that in ninety of a hundred instances of constitutional disturbances at the period alluded to, when the menstruation ceases, the ovaria and the uterine are the sources of disturbance. Nature has established a reciprocal action between the uterus and mammae, and though widely apart, they are intimately united in sympathy. The parts in the pelvis are joined by juxtaposition, sympathy, and community of circulating vessels, but sympathy alone affords an equally intimate union between the ovaria and mammae. Every change in the ovarian circulation has an influence: every change here, as you well know, or ought to know, has its effect upon the mammae; the first period of puberty and the final period of change—menstruation, conception, quickening, delivery—all have this influence. In all these different conditions, the changes in the uterus and ovaria are attended with,

or marked by, pain and turgescence of the mamma. At the final termination of ovarian action—that is, at the “turn of life,”—the irregularity of menstruation produces a most decided influence on the mamma. It is this which lays the foundation of the disease we are to consider; yes, it is the disturbance of the uterine system which, at the change of life, produces irregular flushings of the face and depression of the spirits: we may see the individual flush, and hear her sigh; she then breaks out into perspiration, and the little paroxysm is over. The condition of the female system is said to subject them to inflammation and congestion at this time—to rheumatism and to erysipelas; and all this I can very well believe.

The number of young women, from the age of 16 to 25, who have presented themselves in the hospital with lumps in the breast, is fully equal to those who have presented themselves at a later period of life with carcinoma. We have to trace an influence of the same kind in both—namely, irregular uterine action: that which in the early period of life produces strumous lumps in the breast, at a later period of life will lay the foundation of carcinoma. I take an example from the papers before me. A young woman presented herself in this hospital with an enlarged hard mamma, in the expectation that we would perform the operation of amputation. When the breast was examined, we declared it was not necessary to operate; that the swelling, from her age and her constitutional character, was more allied to struma than to carcinoma; and we did not, and would not, operate; upon which it came out, that, in the country, they had taken off the other breast for a complaint exactly similar to that for which she now presented herself. The young woman was in these circumstances taken into the hospital, and from the remedies employed, by and by the tumor subsided, and she was dismissed cured. This is a remarkable case, but you will see many similar; you will see patients sent up for operation who are suffering from strumous enlargement of the mamma: hence you are to understand that, according to my experience in these matters, the uterine irritation that takes place on the first appearance of change produces swelling and disturbance in the mamma, and that such disturbance will leave after it a tumor of a strumous character; but the irregularity of uterine action taking place at 40 or 50, will not be attended with strumous disease, but with carcinoma—tumors of a worse and less manageable nature. Now this being the truth, it is very important that you consider it, otherwise you will be performing the operation of extirpation

when it is not necessary; and you will observe, that the operation for carcinomatous mamma is considered with a more favourable eye by surgeons in general, because they do not operate in the true carcinoma, but in strumous disease of the breast. They take off scrofulous disease of the mamma, and the patient recovers, and lives long; whereas, were they only to operate when there is true carcinoma, their opinion would coincide with mine, they would be less sanguine—I mean in regard to the favourable termination after the operation of amputation.

What you see in the breast of a female, you see in the glands of the other sex. Suppose, for example, that there is a sore throat, or inflammation in the fauces, and that it produces a swelled lymphatic gland on the side of the throat; in a young man this becomes a scrofulous swelling, and abscesses, such as you see every Thursday among the out-patients. Now contrast these with the case which you have just seen in Hartford ward, where the patient has a scirrhus tumor in the neck. He tells you he had a quinsy—that was internal inflammation, producing action or excitement in the glands of the neck; and these, in a man 50 years of age, have taken on a carcinomatous character, and he is beyond our means of giving relief. The parallel, then, you see, is a just one.

In the next place, as there is a coincidence in time, so is there a considerable resemblance in the nature of the disease which fixes upon the ovaria and the mamma; the difference is chiefly in their position as internal or external parts. This is a very interesting inquiry, because it embraces an extensive view of practice. The scirrhusity, I say, and hydatid tumors, to which the ovaria are subject, would become uncontrollable fungated ulcers were they attached to the skin. On the other hand, many of the hydatid and encysted tumors which infest the mamma, and are the forerunners of so many distressing cases of ulcer and ill-conditioned sores, if they were seated in the ovaria, being internal, would smolder, and partake of a chronic state that would hardly interfere with the term of life.

Let us take our illustrations from some other departments of practice. You know familiarly well that an abscess makes its way to the surface. Why is that? It is not enough to say that it is a sort of intelligence, as Mr. Hunter would describe it, by which the disease makes progress to the evacuation of the matter: that is not the case; it is the consequence of a more general law, that action is more easily excited, and goes to a higher degree, in the surface, than in the deep part; and the

side of an abscess which is next the skin will enter more readily into inflammation, ulceration, and absorption, than the part which is deeper seated, or removed from the surface. The consequence of this law is, that suppuration tends ever to the surface; and you must have remarked, that when an abscess has been in a chronic state, being internal, no sooner does it reach the skin than it becomes highly active—that is to say, the skin inflames, it is rapidly absorbed, and the abscess points and discharges. If you be not convinced of this, take the example of an inflamed lymphatic gland. Suppose there is disease of the penis, and that, either by irritation of a lymphatic gland, or by an absorption of matter, it involves an external gland of the groin in inflammation; the consequence is bubo; but, as anatomists, you are aware that lymphatic vessels go round under the pubes, and into the pelvis, yet you never heard of a bubo within the pelvis. Even authors upon this part of anatomy and pathology tell you that there is no such thing as an inflamed and suppurative gland within the abdomen. They attribute it to Providence. I admire their tone of mind; but without profaneness, I would say the immediate cause is, that the gland is internal, and does not inflame—is not subject to inflammation from a degree of irritation which would cause suppuration in a gland lying immediately under the skin. There is a parallel case in the instance of a ball. A ball, as I stated last week, will accidentally remain some ten or fifteen years in the body, lying close to the vertebræ; but who ever heard of it remaining so long under the skin? No; it will remain quiescent, if deep, producing no re-action; but it will not remain 24 hours without inducing inflammation, if it be just under the skin. The uterus and ovaria are internal, the mamma is external; and when disease at this climacteric period affects the body of the uterus, it will long remain chronic, or quiescent; if it influence the os tincæ, the more external part, it will be more active and more destructive. But even here its rapidity will not be equal to that of the same disease affecting the mamma.

These remarks lead you to comprehend the reason of my very great desire to be particular in

The Mode of Dressing the Breast.

It is to make the mamma, as far as possible, an internal part, or, in other words, to protect it against the changes of temperature, and to give it a gentle and uniform support, and to soothe, not to excite, the skin over the gland. I shall now minutely describe the manner of dressing,

believing that it is a lesson of the first consequence to you.

Whilst the dressings are preparing, let the breast be covered with a flannel fomenting cloth wrung out of a warm lotion (a drachm of extract of conium in a pint and a half of water;) prepare a soft ointment of the empl. thuris and extract of conium, or of mercurial ointment, or with a proportion of the ung. hydriod. potassæ; spread this on long slips of lint, and lay these slips over the tumor in all directions, covering it completely; cover this dressing with a piece of oiled silk, making a little slit for the nipple; over this lay a layer of cotton wadding, so that the breast be uniformly compressed, and the nipple guarded. Finally, swathe the bosom, and lay on each side of the neck shoulder-straps, or the split cloth. Do not be satisfied with recommending the arm to be kept still, but put a turn of ribbon round the arm, and pin it to the side, or let the hand rest on a ribbon round the neck. (A bustling woman will quite defeat your purpose, by the incessant action of the pectoral muscle under the mamma.) This dressing should remain for three or four days.

The best example of the happy effects of this mode of dressing the tumor of the mamma, combined with proper treatment, you have in a woman who occasionally waylays me in the Northumberland ward. The reason is, that she was long an inmate of that ward, and is known to the nurse. Now that patient had an enlarged, hard, and knobby breast, which was by all of us condemned to operation. She refused to submit, and I was constrained to limit my treatment to the mode I have described, and the result has been a complete softening of the gland, and a disappearance of the "scirrhus."

I was led to these remarks on the local treatment of the tumor, by observing that disease of the ovaria or uterus very generally accompanies the disease of the mamma: so that when you see a scirrhus tumor in the mamma, you may be almost certain that there is more or less of the same disease in the uterus or ovaria; but it is not noticed in practice, because there are no prominent symptoms during life. There is scarcely a case, however, in which the patient dies of mammary disease, where you do not find a diseased state of the uterus or ovaria; and therefore, when you come to the question of amputation, you do not merely judge by the appearance of the mamma, by the condition of the glands of the axilla and neck, by the countenance and general appearance of the patient, but also by those symptoms which indicate uterine disorder; and although there be no diseased glands in the axilla, and nothing

very remarkable in the woman's countenance, yet if she be complaining of pains in the loins and hips, and down the thighs, which are indicative of disturbance in the uterine system, I would advise you not to operate, but to endeavour to alleviate the symptoms.

These remarks lead to a distinct object in practice—viz. to remedy the defects of constitution, and allay the irritation of the uterine system.

I have mentioned the constitution of men at that period of life, and may here notice that prostatic disease offers a fair parallel to glandular disorder of the female, and that it is one of the sequelæ of the same condition. I take this illustration. A young man comes to you, saying that he has got disease of the prostate; you are at once aware that he cannot be the subject of the "prostatic disease"—that disease to which old men are subject. In the young man, the prostate gland becomes the seat of a scrofulous abscess, and it will wear out the constitution as effectually as a scrofulous abscess in the lungs; but he is not subject to that scirrhus which is peculiar to advanced years, and therefore you may give him every assurance that he has not the prostatic disease. But if a man of 70 comes to you in the same circumstances, complaining of disturbance at the neck of the bladder, and frequent discharge of urine in small quantities, and if he have neither the symptoms of stone nor a stricture in the urethra, you may be almost assured that prostatic disease is commencing, and that it is of a formidable nature.

I mean by this to remind you, that in men, as well as in the other sex, there is a disease peculiar to a certain period of life, and of the most serious nature—a disease which never takes place at an early period.

In regard to the constitution, to me, who in early life knew the merit and the excellence of Dr. Plummer's pill and diet drink, and its habitual use by the old practitioners of Scotland, it was a matter of surprise, about twenty-five years ago, to see the same treatment become quite the fashion here, under the authority of Mr. Abernethy's name. That gentleman had the unhappiness, I must say, to estimate public opinion very low; and singularly enough, the manner in which he marked his contempt, became the source of increasing popularity. I speak of this, because I am apprehensive that the admiration of Mr. Abernethy's practice may have gone too far, and produced a sort of re-action, and it may now be too much neglected; but it is founded in extensive observation, and is not to be lost sight of: you must not lend yourselves to mere

fashion in these things. The system of old Dr. Plummer, which was to give his well-known pill at night and his diet drink, and to send his patient to the mountains to drink goats' milk, was effectual to the destruction of a variety of local diseases; and every apothecary in the northern part of the island knew this well long before Mr. Abernethy took it up; and therefore, from that long experience, and from the experience and authority of Mr. Abernethy, you must not throw it lightly aside. The blue pill and the bitter purgative draught are good; the compound calomel pill and sarsaparilla are good, for they are the means of exciting secretion in the bowels, at the same time that they soothe them by removing what is irritating. The bowels may be disturbed, and yet neither pinch nor give pain in any way; but they may produce irritability of temper and of constitution, or nervous depression, and thus lay the foundation of organic disease.

With respect to the great leading cause of all, in these diseases of women—viz. irregular and disturbed menstruation, it may be taken as a pretty general rule, that it must be treated by cooling regimen, the tepid shower-bath, the warm salt-water bath, friction of the whole body and loins, gentle exercise in the open air, and change of residence, if circumstances will admit of it. Travelling imposes on the rich and indolent a condition the most nearly approaching to that state of nature and of freedom which the peasant has by necessity. There may be found, in the cases that I lay before you, notices of women of corpulent habit, and in apparent health, but with pains in the breast, enlargement of the belly, sickness, and suppression of the menses; and such women, unless much care be taken, will have confirmed scirrhus. I will select a case of this, and give you a remarkable instance, because it is imagined that these sores never heal.

"Jemima Malone, 45 years of age, the mother of ten children, the youngest eleven years of age, four years ago first perceived a lump in her right breast, of the size of a marble. In the course of a year it had acquired the size of an egg. Two years after its commencement, she applied at St. George's Hospital, where she was recommended to have the breast removed; but to this she would not consent. The nipple at this time was not drawn in. About six months ago, the breast became discoloured, numerous small lumps formed round the larger tumor, and soon afterwards it became ulcerated and painful. The ulceration has since gone on gradually increasing, till it has attained its present immense extent. The tumor occupies the greater part of the right side

of the chest; the central point is deeply ulcerated, and sloughing around the ulcerated part, for about two inches. The skin is of a dark blue colour, and studded with small hard tubercles."

Gentlemen, you will at once acknowledge that this is an aggravated case of carcinoma. The report proceeds—"She still menstruates, and has always done so regularly: at the period of menstruation the breast bleeds. She has no difficulty in breathing, but has constant dryness of the fauces, which awakes her in the night with sudden choking."

Now the case of Malone proved to be one of the most remarkable that has occurred for a long time, from the complete closing and cicatrization of one of the most malignant cancers. The circumstances of the case are still fresh in the recollection of every body. Her name appears in the books from June to November, 1830. When this patient came to the hospital, she was remarkably stout, with a full, ruddy face, altogether of the robust landlady appearance. She had this open cancer in one breast, and the tumor was of unusual size—fully half the size of the head. The nipple was eaten away by ulceration; a deep foul sore occupied the centre; the edges of the sore were abrupt, rugged, tuberculated; altogether this was the worst and most formidable case that the surgeon could well look upon. The remarkable circumstance was, that in the course of a few months the woman's whole appearance became altered; and it was obvious that a great constitutional change had taken place. She was always a timid and effeminate creature in disposition; but the robust, blown appearance, left her completely, and she became spare and thin, and her face pale, having now more the look which belonged to her real disposition. In the meantime a most astonishing change took place in her breast. The great mass fell low, the huge crater closed and gradually cicatrized, the edges of the ulcer also healed, and the appearance is now very remarkable. There was still the excavation and rugged edge, but the skin whole, and there was every appearance of a complete subsidence of that action which some months before seemed so very formidable.

It will be anxiously inquired, what was the treatment in this case. There was no specific medicine, but only that system pursued which I am anxious you should follow in these cases. I have already mentioned to you a patient who occasionally comes here on a Thursday, who had a tumor which, on a full consultation, was condemned for operation; but it has entirely disappeared, and there is now no

disease whatever. These cases are important, because they furnish us with some hope that, even when circumstances are exceedingly bad, there may be an amelioration and cicatrization of the tumor.

When the menses stop suddenly, and return with a hæmorrhagic character, we can but suspect some disease already commenced in the uterus, and the *flow of blood*—I mark that with emphasis—with unusual pain, proceeds from this source. You are aware that there ought to be no clot. This is a condition which requires the utmost attention. Camphor in pretty full doses, with extract of hyoscyamus and opium, will allay the pain. It certainly is not desirable to see the menses intermit; small bleedings, therefore, are proper enough at this period, and used to be more frequently practised than now. I confidently recommend you to bleed from the hæmorrhoidal vessels, by leeches, once a fortnight. The warm salt-water hip bath has a very soothing influence, when there is pain shooting from the back to the pubes, and tenderness of the spine, which is a very frequent attendant on uterine irritation. Warm fomentations, with anodyne extracts in solution, are proper, applied not only externally, but to the os tincæ and to the vagina, by a well-contrived injecting apparatus: this greatly allays irritation. For example, the mucilage of quince seeds and extract of hyoscyamus or conium, tepid, form an excellent injection for the vagina. The pipe should be passed through a piece of sponge, which makes the injection easy, and does not disturb the parts within. If there be any indication of disturbance in the mamma, a seton or issue should be made in the arm. With respect to the bowels, it may sometimes be proper to use aloes and other warm purgatives, which operate on the rectum and hæmorrhoidal vessels; but sometimes they are to be especially avoided, and rhubarb, senna, and jalap, to be preferred. In cases of threatened carcinoma, a change of diet is advisable—for nothing is so serviceable in inducing a change of constitution. Coffee and milk for breakfast; rice-milk, with cinnamon, in the forenoon; a pudding made with egg for dinner, and milk, or soda-water, and a biscuit or rusk, in the evening, is enough of nutriment. If our patient has been in the habit of taking meat at dinner, a heavy supper, and something comfortable on going to bed, which is the way that the principal part of the patients live who come here, we may expect present advantage from such a mode of living as I advise. The treatment that is adopted, local and general, with advantage, in cases of struma, is also proper when there is a threatening of carcinoma. These were the circumstances

that were attended to with such benefit in the cases alluded to.

For the reasons I have assigned, it is my duty to enter very fully into this subject, but I will give it in small and repeated doses, so that you will not be wearied with me. I may devote half an hour to it occasionally, while at the same time I attend to the common practice of the house.

CONTRIBUTIONS TO THE PATHOLOGY OF THE CHEST.

ULCERATION OF THE LUNGS.

To the Editor of the Medical Gazette.

SIR,

As diseases of the lungs are of vast importance, and when we consider that no less than four distinct maladies, namely, ulceration of the larynx, chronic inflammation of the bronchia, pleura, and substance of the lung, may be, and frequently are, mistaken for true tubercular phthisis, I conceive any thing illustrative of these diseases to be acceptable, especially when it is obvious we can only obtain a more lucid knowledge of each, where their causes and nature are more clearly pointed out. The diagnosis and prognosis, in the latter stages of these diseases, are also difficult: the former, from the sequel of each being analogous, that is, terminating in ulceration and suppuration of the substance of the lung; the latter, from its almost universal, but in some rare instances favourable termination.

The following is a case of ulceration of the body of the lung, originating from chronic inflammation, and in many respects highly interesting. I was assisted in the treatment and management of the patient by Dr. Turner, whose opinion of the case coincides with my own. I have endeavoured to contract the details of it as much as possible; and should you consider it adapted to the pages of your useful journal, its publication will oblige

Your obedient servant,

WILLIAM ROBBS.

South Terrace, Grantham,
Dec. 1, 1834.

Mr. S., aged 39, of sanguineous temperament, fair complexion, with light brown hair, rather above the middle stature, and possessing the appearance of having been a fine healthy-looking

man. For some years he filled the situation of guard on one of the York coaches running to London. In the autumn of 1832 he was attacked with pneumonia; for this disease he was under the care of Dr. Balcombe, of York, from whom I received the following account:—

“Mr. S. has laboured for some time under a subacute form of pneumonia, which has yielded to repeated local bleedings and blisterings; this occurred some months ago. Within these last few weeks there has been a recurrence of the attack, but in a much milder form. The chief symptoms have entirely subsided, but there still remains a spitting of bloody matter, which shews some ulceration of the body of the lung, and it is of much importance that it should be watched.”

June 5th, 1833.—At this time he went to Leamington, where he made use of the Leamington water and shower-baths. After this he spent two or three months in Leicestershire; from thence he came to Grantham, without having received any relief. I was first called in attendance on the 4th of October, 1833. He then presented an emaciated appearance, had a troublesome huckling cough, and expectorated about a quarter of a pint of bloody mucus, mixed with purulent matter, in the twenty-four hours. His appetite was tolerably good, but he suffered great flatulency after a full meal, and his cough became more troublesome. The circulation of the blood was regular, the pulse never exceeding 96 in the minute. He complained of a burning pain in the throat, palms of the hands, and feet; a dull pain of the left side, with a very oppressive sensation at the pit of the stomach. Bowels costive; great lassitude; no chilliness; no night sweats; no hectic fever. His sleeps at night were short and disturbed; he was able to lie on the right side, but whenever he attempted to turn on the left, he eructated large quantities of gas, which he said smelt like the Harrowgate water. There appeared an unnatural bulging of the left side of the chest. On percussion and auscultation, the right lung performed its office naturally; the left, at its superior part under the clavicle, was dull; and on the application of the stethoscope, the mucous rattle was distinct. At the inferior and posterior part, the respiratory murmur was not distinguishable; more anteriorly, and

between the sixth and seventh ribs, just below the left breast, pectoriloquy was very distinct; and when the patient coughed, a gurgling noise was heard. He was ordered to apply the tartar emetic ointment to the affected side of the chest, and take the balsam copaiba, as recommended by Dr. Armstrong. He persevered in this treatment till considerable irritation of the skin was effected, as well generally as locally; but the symptoms continued unmitigated, and if any thing the expectoration increased in quantity, and became more sanguineous. Animal food appeared to exasperate the cough and expectoration; he was consequently ordered to discontinue it.

Oct. 24th.—He was much weaker; the pulse 86, and natural; the tongue slightly furied; desire for food not so great; and in other respects much the same.

R Quin. Sulph. gr. iv.; Conf. Aromat. q. s. ft. pil. ter in die. Emulsio Amygd. c. Tinct. Camph. Comp. tusse urgente.

27th.—He was stronger, and improved; the cough and expectoration continued; pulse regular and natural; bowels obstinate.

To have clysters administered as occasion might require. To continue the other remedies.

30th.—A small blood-vessel appeared to have given way in the substance of the lung; there was a considerable expectoration of mucus, mixed with fresh arterial blood; this produced very depressing effects on the patient, with profuse perspiration. The quantity of blood did not amount to more than between two and three ounces.

R Plumbi Superaect. gr. j.; Pil. Rhei Comp. gr. v. 6ta hora sumend.

31st.—The expectoration of bloody matter continued, but did not appear fresh; the patient had recovered from the depression he suffered yesterday; there was slight vascular excitement.

Pergat.

Nov. 4th.—The expectoration had become thinner, more in quantity, and slightly tinged with dark-coloured blood. He complained of his cough, a fluttering pain in his left side and pit of the stomach; also rheumatic pains of the left arm, which prevented him sleeping the fore part of the night. Appetite good; tongue clean; no evening exacerbations of fever.

R Pil. Opii, gr. j. h. s. sd. om. nocte. Pergat.

6th.—The bowels constipated; in other respects the same.

Sumat. Ol. Ricini, p. r. n.

10th.—The expectoration had increased in quantity, become thinner, and less tinged with blood; no fever; no night sweats; and in other respects much the same.—Pergat.

16th.—Slight pyalism from the head; the expectoration amounted to nearly a pint in the twenty-four hours; complained of gripping pains of the abdomen; bowels rather slow.

R Infus. Rosæ, c. Mag. Sulph. p. r. n. Continue other remedies.

17th.—He had thrown up several pieces of organized lymph in the expectoration, which continued very great, and the cough troublesome.—Pergat.

18th.—A large quantity of arterial blood had been voided by expectoration, amounting in quantity to about four ounces; it was fresh, and frothy. He was in a very depressed state: perspiration very profuse; surface of the body colder than natural; the action of the heart very feeble; pulse scarcely to be felt at the wrist, beating 64 in the minute; tongue and mouth moist. Complained of no pain; said he felt great oppression of the left side of the chest before the bleeding took place, and a very unpleasant smell in his breath. The bleeding came on as he lay in bed, without any apparent cause, and so very rapid as to leave no doubt of a large blood-vessel having given way.

Cont. Pil. ter die; R. Mucil. Acaciæ, ʒj.; Solut. Morph. Mur. ℥xv.; Pulv. Scillæ, gr. ij.; fiat haustus 3tia hora sumendus.

19th.—Had slept about two hours during the night; expectoration small in quantity, highly tinged with blood, but did not appear fresh; slight fever; pulse 90, and soft; had perspired during the night; tongue and mouth moist. On percussion, the left side of the chest sounded very dull. The stethoscope indicated the left lung much louder; the respiratory murmur could not be heard over the lowest part of the chest. There was a crackling noise (metallic sound), as if the air had escaped into the cellular membrane, between the lung and pleura; this was most audible at the

upper part of the chest. Pectoriloquy was not distinguishable.

To continue the pill and draught every eight hours.

20th.—Had slept at intervals during the night, and surprisingly rallied. The expectoration was reduced to about four ounces in the twenty-four hours; it was more purulent, and less sanguineous. Pectoriloquy was again distinctly heard over the space between the sixth and seventh ribs, just before their angles.

Ordered a seton to be placed over the part where the voice was so distinctly heard.—Pergat.

29th.—Complained of unusual heat over the left side of the chest; much griping pain of the abdomen; the gums were swollen, and very dark coloured. The seton discharged healthy pus. The expectoration continued very abundant, containing large quantities of purulent matter, slightly tinged with blood.

Ordered a fold of linen rag, moistened in Spirit Lotion, to be constantly applied over the affected side of the chest.—Perstent omnia.

Dec. 6th.—He had improved; the expectoration continued very abundant; the cough short, and chiefly in the morning. The application of the spirit wash was very grateful. His appetite was good, and diet chiefly confined to nourishing fluids. The circulation of the blood natural; tongue clean; the bowels sluggish; no night sweats; no hectic. The seton produced a good discharge of healthy pus.—Pergat.

16th.—The expectoration still continued, occasionally tinged with blood; colic pains of the abdomen from the head; in other respects he has improved, and gained flesh.

Omit. Pilulæ. R Pil. Opii, gr. iij.; st. sl. et repet. om. nocte.

1834, Jan. 2d.—Colic pains of the abdomen had been very severe at intervals since last report; the expectoration had increased, being not less than a pint in the twenty-four hours, and become more purulent. On percussion over the left side of the chest, under the left breast, more sonorous; over the upper and lowest parts of the chest, more dull. On the application of the stethoscope, the cavity appeared enlarged, pectoriloquy being much more distinct, and heard over a more extended surface; the respiratory murmur over the other parts of

the chest dull, and at the posterior inferior part not to be heard.

Jan. 17th.—For some days past he had complained of a dull heavy pain, and unnatural heat in the left side; had not rested so well at nights; cough troublesome, more deep, and sonorous; the expectoration not quite so much in quantity; the pulse 86, and regular; tongue clean; bowels kept open by enemias.

During the evening he was suddenly seized with expectoration of blood, and the course of a quarter of an hour voided about four ounces of frothy arterial blood; this produced a great state of collapse; pulse scarcely to be felt; surface of the body much colder than natural, and covered with a clammy sweat. Said since the bleeding had taken place, the dull heavy pain had ceased.

To continue the application of the lotion, and take alum whey at pleasure. R Pulv. Kino. Comp. e. Opi. ; Pulv. Aluminis, aa. gr. v. M. ft. Pulv. 2da hora. R Infus. Rosæ. ; e. Magnesiae Sulphatis quarta quaque hora.

12th.—Slept but little during the night; expectoration trifling, and very sanguineous; skin moist, and warm; tongue furred; pulse 96, and rather sharp.

Contr. Pulv. ter die, et Mist. om. mane.

15th.—Has improved in every respect. Expectoration less in quantity, very purulent, and slightly tinged with blood.—Perstet.

Feb. 10th.—His general appearance was much better; he had gained flesh and strength. The expectoration had decreased to nearly half a pint in the twenty-four hours.—Pergat.

March 16th.—He appeared going on well till within a few days, when he complained of a dull heavy pain in the left side; expectoration performed with pain, and slightly tinged with blood; heat of the left side of the chest greater than natural; pulse 86, and irritable; tongue moist, and furred in the centre; no night sweats; no evening exacerbations of fever.

Fiat V.S. ad f. 3vj.—Pergat.

20th.—Since last report there had been an increased expectoration, mixed with dark-coloured blood, and it had the appearance as if a fresh abscess had given way. The heat and pain had

diminished; and in other respects much the same.

Applicetur Empl. Lyttæ lateri sinistro. Pergat.

April 1st.—Suppuration of the lung appeared considerably increased; constitutional symptoms still continue slight. A small blood-vessel gave way about noon, after which he expectorated about three ounces of blood, mixed with pus; considerable collapse followed, but not so great as before.

To continue the application of the lotion. R Liq. Morph. Mur.; Tr. Ferri. Mur. aa. ℥xl. Mist. Camph. ℥iiss. ft. haust. statim sumendus. R Infus. Rosæ, f. ℥iiss.; Solut. Lavend. Comp. ℥xxx. fiat haustus quarta quaque hora sumend.

2d.—The expectoration continued tinged with blood; there was slight fever; and in other respects he was better.

Repet. Haust. ter in die; Cont. Lotio ut antea.

25th.—He complained of a great load over the left side of the chest. The expectoration had not been so free for two or three days; it was slightly tinged with blood, and a coagulum appeared in the sputa.

R Tr. Ferri. Mur. ℥x. ex cyathis aquæ frigidæ 6ta quaque hora, capiat. R Solut. Morph. M. ℥xliv. Mist. Camph. f. ℥iiss. h. s. sumend.

26th.—The expectoration and fresh blood continued, notwithstanding he had slept during the night. He had more vascular excitement than I ever observed him to have before.

Fiat V. S. ad f. ℥vi. R Tr. Ferri Mur. ℥xxx. 3ta hora.

The bleeding appeared to have been hurtful: the hæmorrhage increasing very rapidly during the day, he took a large quantity of the tincture, which caused him to be very sick and faint.

R Solut. Morph. Mur. ℥xxv.; Liq. Plumb. Subacet. ℥x.; Acidi Acetici, f. ℥ss.; Aquæ, f. ℥iiss. fiat haust. hora somni sumendus.

27th.—Had had a disturbed sleep during the night. In the morning there was no fresh blood in the expectoration; the skin was moist; slight increase in the temperature of the body; pulse 96,

and weak; tongue moist. He complained of no pain.

Cont. Haust. nocte manequ. Perstent alia.

May 1st.—The expectoration had increased to nearly its former quantity, but free from blood. He was very weak; his appetite good; no hectic; the lead appeared to be acting upon the system.

Cont. Haustus hora somni.

19th.—The cough and expectoration continued; in other respects he had improved.

Ordered a caustic issue just below the left breast.

May 24th.—The issue discharged healthy matter, and he complained of it causing great heat over the left side of the chest. The expectoration was perceptibly less, but in quality the same.

Pergat.

27th.—For some days the expectoration had been considerably less, but very purulent; great dulness, oppression, and unnatural heat, over the left side of the chest; complained of having a disagreeable smell in his breath, like fresh earth, and said he had the same before the bleeding took place last time. Had not rested for some nights; pulse 96, and rather sharp; tongue covered in the centre with a white fur. About 8 o'clock in the evening, while his wife was changing his shirt, he felt the sensation as if hot water was pouring in the chest, and suddenly commenced expectorating very rapidly arterial blood, till from eight to ten ounces were voided. On my arrival he was in the greatest state of collapse, with the surface of the body covered with profuse perspiration; his hands, feet, and face, were quite cold; the pulse not to be felt at the wrist; the contraction of the heart very feeble: he could scarcely articulate, but motioned his hand to the chest, as the seat of all his distress.

To drink freely of Alum Whey, and continue the constant application of the spirit lotion. Cont. haustus 4ta hora.

28th.—Skin warm and moist; had laid very quiet during the night, but not slept; pulse 100, and very feeble; tongue and mouth covered with viscid mucus; expectoration continued tinged with fresh blood.

Pergat.

29th.—He had coughed up a large quantity of matter, very sanguineous; there was a disposition to fever last night; pulse 96, and very feeble; mouth and tongue more moist, and cleaner; urine small in quantity, and very thick; bowels relieved by clysters.

Remedies to be continued.

30th.—Had slept during the night; in other respects much the same.

Pergat.

June 29th.—Since last report he had gone on improving very slowly; he was not able to walk alone, and scarcely stand; the expectoration had continued varying in quantity, and always of a very purulent quality. There had been very trifling or no disturbance in the vascular system; the pulse continuing about 86 in the minute; the bowels torpid without medicine or clysters; no night sweats; no sickness; and the appetite continued good.

Cont. haustus omni nocte.

July 8th.—Called up, 4½ A.M. He had expectorated about four ounces of fresh arterial blood; he presented the same appearance as on the 27th of May, but the state of collapse was not so great. He had been excessively sick from the commencement, and vomited a large quantity of vitiated bile. To apply the spirit lotion as before.

R Plumbi Acet. gr. ʒ. Pulv. Opii, gr. j. fiat pil. 4tis horis sum.

9th.—The expectoration of fresh arterial blood continued, but not very rapid. He complained of much uneasiness in the left side of the chest; pulse 76, and very feeble; the surface of the body cool, and covered with moisture.

Perstet.

14th.—There was no fever; he rested well at night; pulse 86, and stronger; tongue and mouth moist and clean; the expectoration continued very sanguineous, but not fresh. He had been taken several times with a difficulty of breathing, and as if he should be suffocated; said he felt as if there was something placed in the air-passage, which he was unable to expectorate. He has, since last report, expectorated several large pieces of organized lymph, in appearance similar to the lining membrane of the bronchia.

369.—xv.

R Zinci Sulph. ʒss. in aqua tepida lb. ss. Statim sumend. P.

18th.—Had had several paroxysms of difficulty of breathing; expectoration much less in quantity, and contained large pieces of lymph: from their appearances, I believe it to be the lining membrane of the abscess.

To repeat the emetic, and take an anodyne draught every night.

25th.—He had lost the heat of the left side of the chest; respiration more natural; appetite good; his general appearance much improved. He continued occasionally to cough up pieces of lymph; the expectoration was nearly all mucus, and in quantity not amounting to more than two ounces in the twenty-four hours.

To continue the draught every night.

August 10th.—Since last report he had expectorated very little, and that mucus. There appeared great contraction of the left side of the chest; his appetite, health, and strength, had improved surprisingly. When he used any exertion, it produced great perspiration and faintness.

To take increased nourishment, and a draught as occasion may require.

From that time he rapidly recovered. I examined the chest on the 29th of November, and found the left side much contracted. Pectoriloquy was not distinguishable; the respiratory murmur more distinct; and in other respects the respiration was natural.

A similar case to the preceding occurred in my practice in the autumn of 1831: to detail it, would be merely a repetition. The subject was that of a pauper, and he was seen by several medical men in this place, as well as by Dr. Hodgkin, of Guy's Hospital, when the poor man, finding his cure almost hopeless, was induced to seek relief. I believe, by all these gentlemen, as well as myself, he was considered to be labouring under tubercular phthisis; there being very distinct pectoriloquy, with profuse expectoration of purulent matter. There were evening paroxysms of fever, and great perspiration during his sleep in the morning, the only favourable symptom being the want of vascular excitement. This case also terminated by the expectoration of a large portion of organized lymph,

which the man placed in spirit of wine; and there was, in my mind, no doubt of it having been the lining membrane of the abscess. After the expectoration of this membrane, the patient's chest considerably contracted, and he rapidly recovered his usual health. The last time I saw this poor man, he was able to get his living by daily labour.

REMARKS.—By the assistance of that simple, but most useful instrument, the stethoscope, I was enabled, from the first, to distinguish the preceding cases from chronic bronchitis; pectoriloquy, which in both instances was very distinctly heard, together with the history and other symptoms then present, left no doubt but that ulceration of the lung, to some extent, had already taken place. But whether that ulceration had taken place from the inflammation having called into existence tubercles, or excited those which might have already existed into active action, or whether the continuance of the inflammation had created an abscess in the substance of the lung, and so produced ulceration, was a question of vast importance in our prognosis, and one not easy to decide. In all cases where there exists a vomica or imposthume in the body of the lung, there requires considerable caution in our prognosis; since, in the greatest number of cases, where there existed active ulceration with loss of substance, they have generally terminated fatally; and this has been ingeniously accounted for in consumption (and I presume it holds good in this form of the disease also) by Mr. Bodingford, who states it to be owing to the destruction of the cartilaginous matter in the lung. How far this may be the case I do not know, but I think it quite as plausible that the fatality of ulceration and suppuration may depend on the loose texture of the lung, and the great tendency the pus has to extravasation. I believe it is difficult, and sometimes almost impossible, to distinguish in the advanced stages of ulceration and suppuration of the lung from inflammation, between it and tubercular phthisis. There was some difficulty in coming to a direct diagnosis in the preceding case. The cough was short, tickling, and the expectoration slight, except early in the morning; there was great emaciation;

the sleep was frequently disturbed; and some nights he was tormented with horrid dreams. But he had no night sweats, no concomitant hectic, no frequent change of the countenance, which are always present in true tubercular phthisis; and above all, the pulse never ranged more than 96 in the minute. This last symptom has been particularly insisted on by Mr. Maclure, as assisting in our prognosis, in a paper published in the 13th volume of the *MEDICAL GAZETTE*. But that gentleman relates his as a true case of tubercular phthisis; I consider it a symptom of importance in our diagnosis of ulceration without the presence of tubercles. We had also considerable redness and heat about the upper part of the pharynx; but this I have frequently observed in true phthisis.

As the case advanced, it became more doubtful whether tubercles were not present. There was on the 20th of March a sudden expectoration of matter mixed with very dark-coloured blood, as if it had just been evacuated fresh from an abscess. Previous to this he complained of more heat and oppression than common over the affected side; but what was most to have been expected was shivering, sickness, irritative fever, and vascular excitement. The absence of these symptoms constituted one peculiarity of the case. The frequent discharge of blood shewed that the ulceration was progressive, and that the blood-vessels themselves were enveloped in the disease. The frequent and large quantities of blood which were voided, without producing great constitutional irritation, I think is unprecedented. It cannot be surprising that my learned friend, Dr. Turner, as well as myself, should have been mistaken in our prognosis, if we take into consideration that on the 26th of April and 11th of May, we left the patient in a state of collapse, from which we could scarcely expect him to rally.

Abscess of the lungs, originating in chronic inflammation, generally terminates speedily and fatally. Dr. Armstrong has related two cases where the disease was attended with symptoms, and put on the character, of an irregular ague; ulceration of the lung not having been suspected during the life of the patient. The preceding case admits a question whether tubercles were first excited, and softened down in the usual

way, or whether two or more abscesses were formed from the continued inflammation. I am inclined to agree with Dr. Turner in thinking that the latter was the case; otherwise we should have had greater constitutional derangement, and consequently the disease have proved fatal.

I attribute the favourable termination of both cases to the formation of organized lymph, which seemed to have been the barrier to the further progress of the disease. The expectoration of this adventitious membrane, and the contraction of the affected side, were favourable to the patients' recovery.

In the treatment of both cases the patients were ordered to be kept in a warm room, never below 65°, and to live principally on suction. The superacetate of lead in each was given to a considerable extent. I question its beneficial effects. The muriate of morphia is decidedly to be preferred to opium, in allaying nervous excitement, without producing the severe headache and constipation which the latter remedy is apt to do. Throughout the case the bowels were obstinately constipated; probably owing to the liver sympathising with the affection of the lungs. The first venesection appeared to prevent an attack of the hæmorrhage: the blood contained a large quantity of serum, and the crassamentum was both cupped and buffed; the second abstraction of blood was decidedly injurious. The application of external irritants was not attended with that manifest relief I anticipated.

The application of the spirit lotion, as recommended by Dr. M. Hall, in the 13th volume of the *MEDICAL GAZETTE*, was particularly grateful to the patient: and although it possessed considerable influence in checking the hæmorrhage, yet it did not prevent its returning. I have frequently found this latter remedy, when applied as recommended by Dr. Hall, a great acquisition in the treatment of hæmoptysis and incipient phthisis: it doubtless deserves the attention of the profession.

W. R.

Grantham, Dec. 4, 1834.

CASE OF MALFORMATION OF THE HEART.

To the Editor of the Medical Gazette.

Sir,

I BEG leave to forward you the following account of a very unusual malformation of the heart which lately presented itself to my observation, in order that it may be made public through the medium of your valuable journal, should you consider it sufficiently interesting.

I am, sir,

Your obedient servant,

JOHN C. BLOXAM.

Newport, Isle of Wight,
December 8th, 1834.

Fanny B—, the sufferer under this curious structure, died at three years of age, very much emaciated, and smaller than many children only one year old. On opening the chest, the heart was immediately seen, of an enormous size compared with the growth of the child, lying transversely in the chest, with the auricles quite on the right side. The right auricle was greatly distended with blood, and in this state the heart was full three inches from apex to base, and of a corresponding breadth. The aorta, which contained venous blood, was disproportionately large, but otherwise of normal structure: the pulmonary artery, on the other hand, was so small as entirely to escape observation at this stage of the examination. The right auricle, the largest and most hypertrophied of the four cavities, was, in every respect, in the highest state of development; and the left, in the lowest. The parietes of the right ventricle, at their thickest part, measured one quarter of an inch, and those of the left nearly half an inch: the muscular fibre was firm, and the valves naturally formed. The foramen ovale, instead of being obliterated, would have admitted a goose-quill, but retained its valvular form sufficiently to render its temporary closure practicable. The aorta took its origin equally from both ventricles, and communicated as freely with one as with the other. The pulmonary artery opened only from the right ventricle; its parietes were extremely thin, and it was altogether so diminutive that its existence was discovered only by tracing its branches backwards from the lungs: it was there

perceived on the posterior surface of the heart, collapsed, and bifurcating immediately on its exit, so that the trunk was not, in any part of its circumference, above a line in length: hence the case might have been liable to have been mistaken for one of total deficiency of the pulmonary artery.

A short history of the case during life will perhaps prove acceptable. Some days after its birth, the child was observed to be unusually dark, and this colour gradually became deeper. When about two or three weeks old, she was attacked with convulsive movements of the muscles of the face and arms, which recurred at shorter and shorter intervals, and were subsequently attended with great restlessness and uneasiness, an aggravation of the dark colour of the skin, and loss of sight. Any circumstance that excited or irritated the child was found to occasion these "fits", (as they were termed), and for some months previous to her death, she was, for the most part, in an extremely restless and uneasy state, with occasional intonations, which bore all the appearance of approaching dissolution.

ANATOMY OF THE MEDULLA OBLONGATA.

ANSWER TO MR. MAYO'S OBSERVATIONS.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to address to you a few words, in answer to Mr. Mayo's observations, in the last number of your journal, on my uncle's, (Sir Charles Bell's), last paper to the Royal Society, describing several new and highly-important points in the anatomy of the medulla oblongata.

Mr. Mayo has broadly denied his facts. He is well aware, from the general tenor of Sir Charles Bell's conduct towards him, on former occasions similar to the present, that he will not make any answer to his strictures.

Notwithstanding the numerous attacks which Mr. Mayo has lately thought proper to make, through the medium of your journal and otherwise, upon the character of Sir C. Bell as an anatomist and physiologist, Sir Charles's conduct

towards him in this hospital, as his colleague, has been uniformly marked by the most scrupulous politeness; and I take this opportunity of stating, that I have never known him, even under the most trying circumstances, to express the least disrespect towards Mr. Mayo, either by word or deed, in the presence of any of the pupils, or on any occasion, at the hospital, to allude to Mr. Mayo's claims as a physiologist. Mr. Mayo's conduct has been different, and such as to lead me, however unwillingly, to break through the rule I had laid down for myself on being appointed to an official situation under him, never, while I held that office, to enter into any discussions on the subject of his pretensions to my uncle's discoveries in the nervous system.

The other day, in the dead-house, in the presence of a number of pupils, Mr. Mayo asked me if I had seen the paper above alluded to. I said I had. "Well," said he, holding a portion of recent brain in his hand, "a decussation or union of the posterior columns of the spinal marrow is there described." "There is no such thing." "I will show you;" and he proceeded to separate the posterior columns with the scalpel. I told him I had both seen and made the dissection, and knew its delicacy and difficulty; and that it was impossible to show any thing, either one way or another, on the soft brain. He then asked me if he was dividing any thing, and proceeded in his demonstration. I answered, that he was separating the lamina of the septum, which, if he dissected carefully, on a well-hardened brain, and followed downwards to its termination, he would readily find the decussation. He answered, "Exactly, but I have been familiar with the hardened brain ever since I entered the profession, and have often looked for a decussation, and know that no such thing exists."

Now it was evident to me that he did not even know the septum which was to lead him to the union of the columns, and without a careful dissection of which it was scarcely possible that any man could discover the decussation. And I understood the plain English of this public demonstration, directed to me, in my own den, as it were, to be—your uncle and master is a fool, and a visionary; and you were deceived when you thought you saw it, and I now call upon

you to confess it. This sort of demonstration was publicly repeated in a triumphant manner to Sir Charles Bell's apprentices and more immediate pupils, and more than once to myself, so as in a manner publicly to call upon me to answer his objections.

If the discussion of the anterior columns, which nobody now thinks of denying, was a matter of dispute among anatomists for twenty years, we cannot be surprised that Mr. Mayo should not have succeeded, in the one short week that the paper alluded to has been before the public, in finding that which has been described in the posterior columns; confessedly a much more difficult piece of anatomy, even if he used hardened brains instead of recent ones, and more especially if he has not followed the method of dissection pointed out by the discoverer. But I confess I am surprised to find him already thus positively denying its existence. On the tone in which this denial is made, every one can make his own comment. Suffice it to say, however, that I have made a dissection of this part, and, as the Hunterian museum is at present closed, have sent it to the museum of the University of London, that every one may have an opportunity of comparing the evidence of his own senses with that of Mr. Mayo.

The mode of making the dissection is this:—a portion of brain that has lain for several months in strong alcohol must be taken; for we are again and again informed, in the course of the paper, that without this requisite it will be in vain to attempt to follow the dissections described. An incision, with a fine knife, is to be made through the outer pellicle, on each side of the calamus scriptorius, and a lamina of transverse fibres, about as thick as paper, can then be separated from the longitudinal fibres of the sensitive columns. When this is separated on each side, it looks like a sort of partition wall between the two columns; and when traced downwards, it is found to terminate abruptly at a point corresponding to that at which the anterior columns commence their discussion on the opposite side. Just below where the septum terminates, bundles of fibres may be seen to pass from the one posterior column to the other.

Since I have noticed Mr. Mayo's de-

mial of Sir Charles Bell's facts, which forms the first part of his letter, it may be well also to notice the addenda, comments, or whatever they may be called, which form the latter half. The tone in which they are written, I have already said, I will leave to the judgment of others.

"There is a point in the anatomy of the anterior pyramids," he says, "with which he (Sir C. B.) is evidently unacquainted, that accounts sufficiently for the pathological phenomenon" (viz the loss of sensation, as well as of motion, on the side of the body opposite to that on which the brain is affected.) "The lower terminal fasciculi of each of the anterior pyramids are not continued into the anterior *fasciculi* of the opposite half of the spinal marrow, but plunge into its *centre*, and therefore should be expected, if they are the route of the *discussion of symptoms*, to cause the loss of *sensation* in the parts supplied by the spinal nerves, no less than the loss of motion."

I believe I know to what "point of anatomy" Mr. Mayo here alludes: it is a sort of knob, or union, between the anterior and posterior columns of the same side, which Sir Charles Bell pointed out to me some months ago, among many other curious points of anatomy in this interesting region, as resting for future investigation. But how the plunging of the fibres of a *motor* column into the centre of the spinal marrow (I know not what part is meant by this expression), or any where else, could account for *sensation* being lost on the side of the body opposite to that on which the brain is defective, I profess I cannot understand.

Again, Mr. Mayo has chosen to go out of his way for the purpose of criticising the engraver; for though a single false line does give the spinal accessory the appearance of arising from a wrong place, it is in the plate only an accessory, and has nothing whatever to do with the demonstration.—I am, sir,

Your obedient servant,

CHARLES W. BELL,

House-Surgeon to the Middlesex Hospital.

Dec. 21, 1834.

—

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Cours complet d'Histoire Naturelle Médicale et Pharmaceutique, ou Résumé des divers traités concernant l'histoire, la description, les propriétés, et l'usage des substances médicamenteuses, tirées des trois Règnes. Première Livraison. Dulau.

THE progress of natural history in each of its three kingdoms, and more particularly the great advances made in the several sciences collateral with medicine, of late years, have thrown open a vast field for the labour of compilers, though we have not found that, in general, they have hitherto availed themselves of the opportunity. The present work, which is just begun at Brussels, gives fair promise of supplying what medical readers must have long felt as a desideratum—a well-arranged compilation of the objects of *materia medica*. A considerable portion of the animal part is already completed; and for this purpose the *Règne Animal* of Cuvier is largely laid under contribution. Among the other treatises mentioned in the preface as affording ample fund of information in their several departments, we observe Dumeril's *Traité élémentaire*, Richard's *Botanique Médicale*, Drapiez's (who, by the way, is the editor) *Manuels de Chimie et de Mineralogie*, various articles from the two great dictionaries, *D. des Sc. Med.* and *D. des Sc. Naturelles*, and the numerous productions of Barbier, Milne-Edwards, Rattier, Levasseur, Chevalier, Alibert, Lesson, &c. With such resources the Brussels *résumé* cannot but prove a most desirable acquisition for every class of medical men, practitioners, teachers, and *littérateurs*, as well as for students.

Judging from the portion of the work now before us, we should say that most probably it will be well executed: when we have further acquaintance with it, so as to be enabled to form a more definite opinion, we shall speak more positively. The plates are excellent lithographs, of royal octavo size, and will amount to 150 in number. The letter-press will occupy two octavo volumes, in double columns. The price besides

is exceedingly moderate, so that in every sense economy, as well as utility, is primarily consulted.

Des diverses Méthodes pour l'Oblitération des Artères, par LISFRANC; *De la Reunion immédiate des Plaies*, par SANSON; *Memoire comparatif sur l'Hist. Nat. de l'Insecte de la Gale*, par RASPAIL. Dulau.

THESE three productions have just issued from the Belgic press, forming a pocket volume. It is rather a curious collection. The first two, however, have some relationship, being the offspring of the late concours in Paris; but the third might certainly have better made room for the thesis of some other competitor, such as Blandin or Velpeau: as it is, perhaps Raspail's memoir constitutes the principal attraction. It is printed verbatim from the Paris copy, and accompanied by the lithograph plate. By the way, touching the said itch insect, it is a very extraordinary fact that none of our observers have succeeded in detecting it, notwithstanding the minute directions given for the purpose by Raspail and others. From Moutet's remarks in his *Theatrum*, it would seem that he had some personal acquaintance with the *Sarcoptes hominis*, and so perhaps had Sir Theodore Mayerne, as he seems to insinuate in his preface, dedicatory to Moutet. But since that time, three centuries back, nobody has succeeded, in this country, in the detection of the parasite. Baker, Canton, Willan and Bateman, Adams, Heberden, J. Hunter, and numerous others, have failed. We happen to know of some late attempts to find the animal, but they have not been attended with the least success. Is it not likely that the itch in this country is not accompanied by the insect—or that at least the animal is not present in every kind of itch?

Anatomischer Atlas des Menschlichen Körpers, in 84 Tafeln und erklärendem Texte. Von Dr. M. J. WEBER, Professor zu Bonn. Schloss.

THIS magnificent work is now complete, the sixth and seventh parts having just been received in London. Among the objects represented in the sixth *lieferung*, we find the vessels and nerves of the

anterior portion of the system, including the brain, spinal marrow, and the *nervus sympathicus* in situ; the lymphatics, the thoracic aorta, the abdominal vessels, with reference to hernia, &c. In the seventh, the posterior portion of the frame is exhibited, with special regard to the vascular and nervous systems; and among other plates, we observe one representing the descent of the testicles through the rings, and another giving the chief objects in general anatomy. Sir Astley Cooper's work on the Testicle is laid freely under contribution for the former. The Atlas, on the whole, must be seen and examined, in order to be appreciated: mere description might run on to any length, and yet totally fail in conveying an adequate idea of the production.

MEDICAL GAZETTE.

Saturday, December 27, 1834.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

ALLEGED NEGLECT AT HOSPITALS.

THERE are some subjects which our contemporaries take up as never-failing topics of declamation, and on which they ring the changes every time they are at a loss for “a leader”—we mean the abuses which they allege exist in our hospitals. First we are told, that the officers ought to be elected by *concours*, after the manner of France, where the said concours excites more jealousies, more clamour, and more editorial bile (if possible) than the election by canvass and voting among us. Next, we are informed that the business of our hospitals is very badly conducted; that every thing is done in *holes and corners*; that the only object is to cheat the pupils, first out of their money, and then out of their opportunities of acquiring knowledge. Again, we are given to understand that the patients are looked upon as mere pieces of matter, fit to un-

dergo a certain set of experiments; and that they are frequently “murdered” (we use the language of one of our fraternity) for the edification of the physician or surgeon in attendance.

We have often endeavoured to solve the problem, do the writers really believe what they assert?—but we have never come to a satisfactory solution of the difficulty. Mr. Wakley, indeed, the most outrageous of the scribes in question, and who especially treats his readers with stories of “blood,” it is notorious, dare not shew himself within the walls of any hospital in London (excepting always that of the *University*), and, neither knowing nor caring about the matter, evidently writes just what suits his purpose at the moment, and can get up a case for his journal and the newspapers, such as shall make the reader's hair stand on end, without any trouble to himself, though certainly, in many instances, it must be added, without the slightest regard to truth, or even to verisimilitude. This is his peculiar province, in which he stands unrivalled among the writers of fiction; but there are other points in which he is followed by those who ought to know better: for instance, there is a constant cry in the periodicals that pupils are neglected at the hospitals. If there be any hospitals where this is the case, either generally or with respect to individual officers, let them be named; but do not let sweeping charges be indulged in, which, taken as of general application, we most positively and explicitly deny. We challenge the parties in question to come to particulars. Let them give time, place, and person, and we shall know how to deal with them.

The time which the pupil can spend in the hospital, especially during the winter, is very limited, owing to the number of lectures which he has to attend, and probably does not exceed two hours—viz. from 12 to 2, or from half-past

12 to half-past 2; but during this period we know that, at the principal hospitals, every facility is afforded him of visiting the patients with different physicians or surgeons in succession; and if there be any instances in which those gentlemen are not willing and anxious to impart instruction, certainly these constitute exceptions to the general rule. Again, notes of the cases are kept, which are open to the pupils; and in some hospitals, cards are placed at the head of the beds, with every prescription written upon them. The pupils in succession are employed by the physicians as clerks, and by the surgeons as dressers (the former without any additional charge.) In those cases which end fatally, public examinations, without disguise or concealment, take place; and lastly, clinical lectures, or bed-side remarks, are made, so as to impress upon the student the chief points deserving his attention. What, then, would our contemporaries have? It is easy to find fault where criticism is a profession, and where the object is to write *about it, and about it*, to fill up a certain space. There can be no doubt that there was formerly much ground for complaint; but they who deny that very great improvement has taken place, are either very ignorant or very uncandid. True, if there were more time in which to conduct the hospital visits, they might be done better; but while the time is so limited, we doubt very much whether more can be effected to aid the studies of the pupil than is already in operation.

One injury, and a great one, done by those who cry out for "reform" in our hospitals, is, that they lead the pupil to suppose that he has nothing to do for himself, but that all is to be done for him; that if he does not learn, the fault is his teacher's, not his; that he may walk through the wards with his eyes half-shut, without looking and examining, and not-

ing and reflecting, for himself. The hospitals of former times produced John Hunter, and Cline, and Abernethy; and are St. George's, or St. Thomas's, or St. Bartholomew's, in any respect inferior as schools now, to what they were when those great men were students? Are they not, on the contrary, in every respect very greatly superior, in the opportunities and means of instruction they now afford? But these men had eyes, and hands, and heads, which they used for themselves. Let not students of medicine or surgery be deceived, then: the hospitals afford them invaluable *opportunities*; let them only give their attention with a willing mind to the cases, and listen with a candid temper to their teachers, and we are confident they will find every day add something to their stock of knowledge. "*Nulla dies sine linea*," was the maxim of a great artist of antiquity, and we can recommend none better to imitation at the present day.

ENCOURAGEMENT GIVEN TO ANATOMY IN FRANCE.
